This alimentary glycosuria is practically of a regulating nature. If we excite an artificial diuresis, we may produce a glycosuria, when even very moderate quantities of carbohydrates are ingested. In the cases described by Klemperer as renal diabetes, we find a permanent excretion of sugar, though the quantity of carbohydrates ingested is not increased and the circulation is not accelerated by diuretics. In the discussion, Dr. A. Fraenkel opposed the idea of a diabetes strictly renal in character. According to his view the arrest of a glycosuria upon the appearance of a chronic granular nephritis may be readily explained by assuming that the diseased kidney retains the ferment secreted by the pancreas and this ferment in return enables the tissues again to assimilate the sugar. Dr. Fürbringer had seen three patients with diabetes in whom glycosuria ceased as albuminuria appeared. Magnus-Levy had administered phloridzin hypodermically and found that, after doses of even only twenty centigrams the healthy as well as diseased kidneys would excrete sugar, but the largest amount would be excreted by the contracted kidney. These results are diametrically opposed to Klemperer's statements, who says that contracted kidneys excrete no sugar after the administering of phloridzin. The general conclusion of the discussion was that Klemperer failed to sustain his theory of a renal diabetes. Dr. Klemperer also read another paper before the Berlin Medical Society on the prophylaxis of uric-acid concretions in the kidney. The treatment of such concretions in the urinary tract must be principally surgical, because a solution of these concretions by internal remedies is utterly im-

possible, on account of the firmness of the combination of the urates with the organic constituents. Prophylaxis, therefore, is what we must aim at. The kidney should be well irrigated, food substances which aid in the formation of uric acid (as nucleins) must be avoided, and as little meat as possible should be taken, milk, eggs, and vegetables being preferable. Not all nuclein-albumin, however, is turned into uric acid as a final product, for in the case of some its transformation is effected into urea. Certain drugs, such as caffeine, have a strong tendency to increase the formation of uric acid. Muscular exertion also is followed by an increased formation of uric acid. The elimination of uric acid is favored by an excretion of neutral or alkaline urine. Of remedies favoring this Klemperer recommends bicarbonate or citrate of sodium. Urea especially has this property. It may be given in daily doses of twenty grams. It not only increases diuresis, but also is a solvent of uric acid. Piperazin, lysidin, and uratropin are more expensive than urea and of less therapeutic value than it in cases of the uric-acid diathesis.

Of interest was a demonstration at the same meeting by Strauss, who diagnosed a mediastinal tumor with the aid of the x-rays. In the photograph a shadow was to be seen in the thorax as large as a fist, situated to the left of the spinal column. According to Strauss this was a cancerous enlargement of a bronchial gland occurring thorough metastasis, the primary lesion having been in the stomach. Attempts made to locate by means of the x-rays the position of the large curvature of the stomach, after passing a metal sound, have not been successful. During the discussion Boas stated that by his method it was not at all difficult to locate the position of the large curvature by passing a tube. He considered any complicated apparatus for this purpose unnecessary.

At a meeting of the Society for Internal Medicine Krönig read an interesting paper concerning certain new methods of blood examination. One novel procedure was the fixation of blood specimens in hot-air baths. Krönig has constructed a small and a large air bath. The small apparatus is a square metal box, with a receptacle for four specimens. It is placed over a gas flame; a thermometer is attached to show the temperature. With a temperature of 150°C ., the fixation of the specimens is obtained in four or five minutes.

In the large air bath the preparations remain for one hour at a temperature of 115° to 120°C .

At the same meeting Engel reported the discovery of certain peculiar conditions of the blood in diphtheritic children. He examined thirty-two children seriously ill. He found the so-called myelocytes almost entirely absent in those children who recovered. All those (seven) died who had a large number of myelocytes in the blood. Engel calls this condition "myelocythæmia" of diphtheria. All the children were treated with antitoxin. Engel believes that the poison of diphtheria acts injuriously upon the blood-forming structures just as it acts in producing parenchymatous inflammation in various internal organs.

Lacerated Wounds of Fingers.—In cases of severe injury to the fingers by laceration or contusion, put the entire hand into a very ample soaking-wet dressing. Do not trim off any pieces of flapping skin. Incision for drainage is all that is allowable until healing is very well under way. You may then look over the ground and see whether it is necessary to sacrifice anything. A half-inch of boneless finger may be of great value to its possessor.—*International Journal of Surgery*, May, 1896.

New Instruments.

A PORTABLE STERILIZER AND DRESSING RETAINER.¹

By JOHN PRENTISS LORD, M.D.,

OMAHA, NEB.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY, CREIGHTON MEDICAL COLLEGE; ATTENDING SURGEON, ST. JOSEPH'S HOSPITAL, AND CONSULTING SURGEON, PRESBYTERIAN HOSPITAL.

IN the summer of 1894 the author conceived the essential features of the portable steam and hot-air sterilizer and dressing retainer herein described. Thinking that the market would afford something of this character, a search was accordingly made, but with negative results. Sterilizers were too large or too small; the larger were cumbersome and ill adapted to convenient use outside of a hospital; the smaller were inadequate for major operations and necessitated the carrying of a previously prepared aseptic roll for gowns, bandages, cotton, etc., which, as a consequence, were an extra incumbrance, and, furthermore, did not sufficiently simplify the technique of antiseptics in surgical preparations.

It was considered a first essential feature to have a portable receptacle sufficiently large to retain dressings required for any major operation (*i.e.*, gowns for operator and assistants, towels, gauze, cotton, silk, drainage tubes, bandages, etc.), ready packed and primarily sterilized by steam, rendered dry by hot air, and retained in a dry aseptic condition, ready for use in ordinary emergency cases and in convenient order for resterilization in cases of major degree or when extraordinary precautions are desired.

Second, to have an adequate independent heating apparatus for both steam and dry heat, to be used in emergency, but not required when the ordinary means of heating are at hand.

Third, to make the pan for the water not only sup-

FIG. 1.

ply the steam but answer for boiling instruments, either simultaneously with sterilization of dressings or independently, without in any way disturbing the contents of the sterilizer, and also serve as a tray for the instruments, thereby relieving the satchel of this encumbrance.

The apparatus herein described has been in actual use more than a year and a half, with such results as to justify me in presenting it to the profession for their consideration.

The sterilizer, as represented in Fig. 1, is nine and one-half inches wide, ten and one-half inches to the top of the handle, and sixteen inches long. It is made of copper and brass, nickel plated. The handle is hollow. The handle post contains a perforated cork for the reception of a thermometer, after removing the mill-headed cap, *A*. The partial unscrewing of the cap *B* permits the steam to escape, when dry heat replaces the steam. The cover is secured by

¹ Read before the Medical Society of Missouri Valley at Sioux City, Ia., March 20, 1895.

clasps or hooks, as represented in the cuts. The pan is fastened to the bottom of the apparatus by hooking its handles over the pins upon the ends of the body of the sterilizer.

Fig. 2 represents the top removed, showing the gal-

FIG. 2.

vanized-wire basket which retains the dressings. This basket is removable and has a double bottom of copper, which prevents scorching of the contents when dry heat is used. It serves also as an aseptic retainer, especially convenient in the absence of plenty of bowls, basins, etc.

Fig. 3 is self-explanatory. A second pan with a

FIG. 3.

wide flange is nested with this and is used as a cover for the instrument boiler, and also as a second tray.

Fig. 4 illustrates the manner in which the flame is

FIG. 4.

limited by the slides in the cover of the alcohol stove. By closing these slides the flame is extinguished. When the stove is used for steam the whole top is removed.

Fig. 5 represents the application of dry heat, with

FIG. 5.

thermometer introduced through the handle.

It is not to be inferred that the sterilizer requires the use of the alcohol stove. Any heat may be used when at hand. The independent heating apparatus is intended for emergency.

The alcohol stove is four by ten inches and one

inch deep. It contains a mat of asbestos wool, which requires twelve ounces of alcohol to saturate, and will burn forty to fifty minutes. Two quarts of water will boil in six minutes, and a steam heat of 212° F. is attained with the sterilizer in ten minutes. The stove is readily packed in the pan, as is also the tin alcohol bottle. The bottle holds one pint, and the remaining four ounces of alcohol, not used for the stove, may be used for disinfecting hands, wounds, site, etc.

The whole makes a compact, capacious combination, all the parts of which are useful and necessary adjuncts to a surgical outfit.

The construction is simple, the apparatus is light and very portable. No new principle is claimed. The apparatus is simply a convenient combination of necessary utensils, all of which are required in emergency work.

The steam heat is abundant and efficient. Under steam is used, but, the air being allowed to pass off through the handle during the first minute or two, perfect saturation and sterilization of the contents by steam takes place, the same practical results being secured thereby as in other sterilizers, which are more complicated and bulky, heavier and less roomy. Besides, they do not furnish pans, etc., which are especially convenient to have in emergency work.

A small size is made for oculists and those who do minor work. Its small size yet considerable capacity commend it to a class of men who are wont to operate without up-to-date aseptis, for the reason that their work is of such a minor character that these extra pains are not deemed necessary in order to get results in the majority of cases; yet bad results are sure to follow this neglect of the only safe course in all surgical procedures.

The small-sized sterilizer is twelve and one-half inches long, five and one-half inches wide, and six and one-half inches high, including the handle; it will hold sufficient gauze, cotton, bandages, drainage tubes, silk, etc., for any minor operation.

The sterilizers are supplied with canvas or telescope covers, and are of moderate cost.

The writer has long considered it necessary for general practitioners, and surgeons as well, to break away from the old and too frequent custom of using gauze and various other dressings from their several packages, which have occupied the dusty shelves of the office for a variable period, and have, perhaps, been opened repeatedly. Gauze should be supplied in less expensive retainers, furnished in blotting paper for instance, with an outer covering of a less permeable character, which latter, when received, could be removed and the gauze with its porous covering kept in the sterilizer ready for use, and resterilized as often as contaminated by opening or using from the retainer.

If all physicians would inaugurate these reforms in the care of their dressings, their results would be much improved and operative surgeons would see fewer cases of septic wounds—the legitimate offspring of a practice much too common, in view of our present knowledge of aseptis. It would seem superfluous to make these remarks to readers of this journal, but all will admit that aseptis in office and general practice has not yet been rendered as simple, effective, practical, and easy of attainment as it should be. It has, therefore, been my aim to simplify it, so far as immediate dressings for the wounds are concerned, by having them all together in one retainer, both convenient for office use and ready for transportation and re-sterilization at a moment's notice; so that, instead of using gauze from one or more different packages, silk from another, drainage tubes from another, cotton from the roll, and bandages from the bottom of a dirty satchel, etc., they are all from one clean, reliable source, absolutely to be depended upon.

Therefore, with sterile dressings, gowns, and towels, boiled instruments, sterile hands, and a clean wound site, no man need fear to make a wound within the range of his ability. And let me here add that if we take away the fear of sepsis our general practitioners will be less loth to cut. My observation of this class of men has been that they usually know when and how to operate, but that the complex and complicated time-robbing methods of preparation, together with their uncertain results, cause them oftentimes to refer their cases to others. At the present day, with the present state of our knowledge, there should not be a hamlet or crossroads where accidental and surgical wounds are not treated aseptically. To simplify and render easy such an attainment is a service to our fellows and a blessing to mankind.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 15, 1896:

	Cases.	Deaths.
Tuberculosis.....	151	124
Typhoid fever.....	37	15
Scarlet fever.....	22	2
Cerebro-spinal meningitis.....	0	5
Measles.....	62	9
Diphtheria.....	114	31
Small-pox.....	0	0

Vaginal Irrigation without Wetting of Clothes.—A. E. Bradley, Captain, Medical Department, U. S. A., now at Fort Yellowstone, Wy., writes:

"One occasionally meets with a new method of accomplishing some certain end; it comes often as a surprise and is so simple that one wonders it had not occurred to him before. It may be that the surprise I received recently is not, to many, a new method of accomplishing vaginal irrigation, but it was to me.

"In obtaining a history the following conversation occurred:

"Do you use, or have you ever used, hot-water douches?"

"Oh, yes; but I thought they only helped me for a time."

"Did you take them lying down?"

"Yes. I used a bed pan formerly, but I always got my clothes wet and the bed too, so that it was a perfect nuisance. But after I used a hammock it went better."

"A hammock!"

"Yes. I hung the hammock in my bedroom, got my fountain syringe ready, placed a tub under the hammock; then I lay down, and could use all the water I wanted without getting anything wet. You know the water will run right through hammock meshes."

"Who told you how to do this?"

"No one; I thought it out myself."

"I refrain from comment. This method has advantages appreciated by my patient at least."

Henry Dunant, founder of the Geneva Convention and the Red Cross, his life work, and the part taken by women in this work, was the title of an address delivered by Dr. Jordy before the Berne Good Samaritan Union, November 24, 1895. We are told that Dunant came of a good Geneva family; like all noble men he owed much to a superior mother. At the battle of Solferino, in 1859, he distinguished himself in

the care of the wounded, and through his little book, "Un Souvenir de Solferino," interested Queen Augusta of Prussia, the Empress Eugenie, and other high personages, and finally succeeded in getting together the Geneva Conference of 1864 and in founding the Society of the Red Cross, the members of which care for the injured, more particularly in times of war, but also in times of peace, and are recognized as non-belligerents by the several nations who have adopted the rules of the convention. Dr. Jordy thinks George Sand's desire to credit Arrault, a Frenchman, with being the originator of the Geneva Convention is due to chauvinism. While a number of persons had suggested the idea of recognizing the wounded in battle as neutrals, he thinks there cannot be the least doubt that Dunant's work and writings first led to practical results and finally to the Geneva Convention. In 1867 Dunant had the misfortune to lose his own property and that of relatives in some venture in Algiers, and he is now living in obscurity and poverty.

Advice to Bicyclists.—Dr. Rocheblave gives the following advice: 1. No one should ride until after an examination by a physician. This examination should be made both before and after a walk or run, for some cardiac lesions manifest themselves only after a state of fatigue. 2. Ride no faster than twelve kilometres an hour. 3. As far as possible guard against the desire to ride any faster. It is very difficult not to give way to the "delirium of swiftness." With a light machine on a good road an amateur may easily make twenty-five kilometres an hour. This is too much, for the pulse is increased to 150, even at fourteen and sixteen kilometres an hour.—*Pacific Medical Journal*.

Pure Milk for Brooklyn.—Health Commissioner Emery has appointed a dairy inspector, whose duty will be to investigate the sources of the entire milk supply of Brooklyn. He is charged with the duty of examining the cow stables, the number of animals therein, their sanitary condition, the water they drink, and the drainage of the stables. If in his opinion any feature of any of the dairies is unsatisfactory, he has power to prohibit the sale in Brooklyn of the milk from that establishment.

Venereal Disease a Sufficient Cause for Divorce.—The Paris Court of Appeals recently decided that the fact of marrying before being cured of a venereal disease and knowingly communicating it to the other party in the marriage, is sufficient cause alone to allow a divorce.—*Semaine médicale*.

The Bicycle should be prohibited to women during menstruation.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

SOME STUDIES OF THE BLOOD IN THYROID FEEDING IN INSANITY.

BY MIDDLETON L. PERRY, M.D.,

MORRIS PLAINS, N. J.,

ASSISTANT PHYSICIAN AT THE NEW JERSEY STATE HOSPITAL.

THAT decided changes in the mental state may be produced by thyroid feeding is now a well-recognized fact. This has been demonstrated in numerous cases of myxœdema and cretinism which have made marked improvement under continued treatment with this drug. Recently there has been a number of cases of insanity reported as improved, and some have gone on to complete recovery on a similar line of treatment.

In the first class of cases (myxœdema and cretinism) the treatment by the administration of some preparation of the thyroid gland is entirely rational. The gland in the patient is either defective or absent, and it is simply sought to restore to the system some principle which it has lost thereby, and which is essential to health. But the use of this remedial agent in mental diseases in patients who have apparently healthy thyroid bodies is as yet entirely empirical. Several theories have been advocated as to the manner in which the drug probably acts, but as yet very little has been done toward placing this form of treatment on a scientific basis. So good an authority as H. C. Wood, in a recent lecture on animal extracts, delivered at the University of Pennsylvania,¹ merely says on this subject: "Thyroid extract is sometimes useful in melancholia, but how it acts we do not know."

The object of the work reported below has been to endeavor to throw some light upon the physiological action of this agent. If the result has been such that it will induce others to pursue the subject further, that facts may be established which will place this method of treatment on a more rational basis, the writer will feel that his work has not been in vain.

The present paper is a report of a study of the blood in a number of cases before and during a course of treatment with thyroid. I have made no attempt at a chemical analysis, but have restricted my observations to the numerical and morphological aspect of the corpuscles. And in consideration of the fact that the function of the red blood cell is largely, if not wholly, as an oxygen bearer, I have devoted the most of my attention to the leucocytes.

The only reported study of the leucocytes in thyroid feeding with which I am acquainted is a report of a case of infantile myxœdema by M. Labraton.² In this case the author makes only two examinations in a period of time covering more than a year. This is far too small a number of observations to establish any facts in the case.

The method which I have pursued in making the examinations is as follows: The number of red and white blood corpuscles in a cubic millimetre of blood was first determined by the Zeiss-Thoma apparatus.

It has been my aim to obtain as nearly accurate results as possible. To do this I have in all cases used a dilution of 1 to 200 for the red corpuscles and counted the number of cells in one hundred squares; for the white cells a dilution of 1 to 20 was used, and the entire number in the four hundred squares was counted. Frequently several counts would be made at one examination and the average taken as the result. By reference to Abbey's table of probable errors in counting the blood corpuscles, it will be seen that by the above method the greatest probable error would be less than two per cent. To avoid error from digestion leucocytosis and to insure a similar condition in each case, the counts were all made between eleven and twelve o'clock, and several hours after a meal.

A differential count of five hundred leucocytes was then made. The films of blood on a cover glass, being dried, were fixed in absolute alcohol from two to five minutes and subjected to a contrast stain. The staining fluid used in the beginning was the triple stain of Ehrlich, but this was discontinued for one of hæmatoxylin, orange, and fuchsin, which has been much more satisfactory. The formula used is:

Hæmatoxylin, Delafield's sol	gtt. viij.
Orange G, $\frac{1}{2}$ sat. aqueous sol	gtt. x.
Fuchsin S (after Weigert), $\frac{1}{2}$ sat. aqueous sol	gtt. i.
Water	cc. xv.

The covers are passed immediately from the alcohol into this fluid and allowed to remain fifteen minutes, washed in water, and mounted in balsam. The stain should be fresh, as it soon deteriorates. Owing to the varying strength of hæmatoxylin, slight modifications of the above formula are at times necessary to obtain the best results.

I have followed Ehrlich's classification of the different varieties of white corpuscles into: 1, small mononuclear, or lymphocytes; 2, large mononuclear, including the transitional forms; 3, multinuclear neutrophiles; 4, eosinophiles. He gives the relative number of each variety in normal blood as: Small mononuclear, 15 to 25 per cent.; large mononuclear, 6 per cent.; multinuclear, 70 to 75 per cent.; eosinophiles, 1 to 5 per cent.

Some recent authorities are inclined to give the percentage of lymphocytes somewhat higher and the multinuclear form slightly less than the above, and this has been my own observation. Dr. Walter A. Wells, in an article in the *Medical News* of March 14, 1896, places the normal number of lymphocytes as high even as twenty-eight per cent.

In each of the cases given below one or more counts, both numerical and differential, were made preliminary to the course of thyroid, and during the treatment, generally lasting from a week to ten days, a count was made every second or third day.

CASE I.—M. M—, female, aged thirty-four. A case of mania of puerperal origin and nearly one year's duration. Emotional state decidedly exalted. Physical condition very good. Temperature, 99.2° F.: pulse, 65. Patient was put to bed and two blood counts were made on different days, and the average was taken to establish a preliminary count, which was: R. B. C., 4,832,000; W. B. C., 11,000. Differential count:

¹ University Medical Magazine, April, 1896.

² Gazette Médicale de Paris, January 19, 1895.

Small mononuclear, 18.4 per cent.; large mononuclear, 9 per cent.; multinuclear, 70 per cent.; eosinophiles, 2.6 per cent. She was then put on thyroid extract, ten grains three times a day. The extract was of such strength that fifteen grains represented one sheep's thyroid.

Second day of treatment: Mental condition unchanged. Pulse, 95; temperature, 99.2° F. Blood count: R. B. C., 6,272,000; W. B. C., 9,000. Differential count: Small mononuclear, 17.2 per cent.; large mononuclear, 8.2 per cent.; multinuclear, 74.2 per cent.; eosinophiles, 0.4 per cent.

Fourth day: Pulse quickened; skin flushed; temperature, 99.6° F. General condition good. Mentally exalted. Thyroid extract increased to forty grains a day. Differential count: Small mononuclear, 25 per cent.; large mononuclear, 8.8 per cent.; multinuclear, 64.6 per cent.; eosinophiles, 1.6 per cent.

Seventh day: Patient quiet, but still mildly exalted. Pulse, 106, somewhat irregular; temperature, 99° F. Taking thyroid extract, fifty grains a day. Blood count: R. B. C., 4,520,000; W. B. C., 5,200. Differential count: Small mononuclear, 37.6 per cent.; large mononuclear, 11.6 per cent.; multinuclear, 50 per cent.; eosinophiles, 0.8 per cent.

Ninth day: Twenty-four hours after thyroid was discontinued the patient was still decidedly impressed with the drug. Pulse, 105; temperature, 99° F. Much more quiet. Differential count: Small mononuclear, 26.6 per cent.; large mononuclear, 12 per cent.; multinuclear, 60.4 per cent.; eosinophiles, 1 per cent.

A note made five days later states that she was more quiet and rational than for months past. Patient continued to improve with an occasional period of a few hours' excitement, and made a complete recovery.

CASE II.—S. A.—, male, aged forty. A case of mania of six months' duration. Emotional state exalted. Talk rambling and disconnected. Has had double hæmatoma auris. Physical condition very good. Temperature, 98° F.; pulse, 65. Preliminary blood count: R. B. C., 5,616,000; W. B. C., 8,600. Differential count: Small mononuclear, 31 per cent.; large mononuclear, 6.8 per cent.; multinuclear, 61.4 per cent.; eosinophiles, 0.8 per cent. He was then put on thyroid extract, thirty grains, the equivalent of two sheep's thyroids, a day.

Third day of treatment: No change whatever mentally. Temperature, 98.6° F.; pulse, 75. Thyroid increased to thirty-six grains a day. Differential count: Small mononuclear, 32.6 per cent.; large mononuclear, 5 per cent.; multinuclear, 59.8 per cent.; eosinophiles, 2.6 per cent.

Fifth day: Patient decidedly impressed by the drug, of which he is taking forty-five grains a day. Pulse, 84; temperature, normal. Mental state decidedly exalted; talking constantly. Blood count: R. B. C., 5,440,000; W. B. C., 9,200. Differential count: Small mononuclear, 45.6 per cent.; large mononuclear, 6.6 per cent.; multinuclear, 45.8 per cent.; eosinophiles, 2 per cent.

Seventh day: Somewhat more quiet, but still maniacal. Pulse, 85, tension very much diminished; temperature, 98.2° F. Taking thyroid, fifty grains a day. Differential count: Small mononuclear, 43 per cent.; large mononuclear, 6.4 per cent.; multinuclear, 50.2 per cent.; eosinophiles, 0.4 per cent.

Eleventh day: Patient markedly under the influence of the drug. Pulse, 102, and quite characteristic; temperature, 98.4° F. He is quiet and his facial expression is much brighter. Thyroid has been diminished to thirty-six grains a day. Differential count: Small mononuclear, 34.6 per cent.; large mononuclear, 10.2 per cent.; multinuclear, 54 per cent.; eosinophiles, 1.2 per cent.

Eighteen hours after last dose of thyroid: Patient

quiet but rather disconnected in his talk. Temperature, normal; pulse, 96. Blood count: R. B. C., 4,368,000; W. B. C., 5,200. Differential count: Small mononuclear, 37.2 per cent.; large mononuclear, 7.2 per cent.; multinuclear, 53.4 per cent.; eosinophiles, 2.2 per cent.

Five days after treatment was discontinued there was a very decided change in his mental condition. Emotional state entirely normal. An extract from the case records says he was very much better and talked quite rationally. He took a lively interest in things about him and read the newspapers, something he had not done for a long time before. Blood count: R. B. C., 5,136,000; W. B. C., 6,800. Differential count: Small mononuclear, 45.6 per cent.; large mononuclear, 7.2 per cent.; multinuclear, 45 per cent.; eosinophiles, 2.2 per cent. The change in the mental state and the improvement noted above, while quite pronounced, was of only a few days' duration, when the patient relapsed into a maniacal condition, very similar to that before the course of treatment was begun.

CASE III.—K. S.—, female, aged thirty. Case of simple melancholia of five and one-half months' standing, this being the second attack. Some improvement had been made, but it was slow and her mental state had been unchanged for some time past. Mildly depressed. General health good. Pulse, 60; temperature, 98.2° F. Average of blood counts made on three successive days preliminary to treatment: R. B. C., 4,832,000; W. B. C., 8,800. Differential count: Small mononuclear, 25 per cent.; large mononuclear, 8.4 per cent.; multinuclear, 63 per cent.; eosinophiles, 3.6 per cent. Desiccated thyroid, twelve grains of which represented one sheep's thyroid, was given in doses of ten grains three times a day.

Fourth day of treatment: No change mentally. Temperature, 99.6° F.; pulse, 98, rather quick. Complaints of pain in the extremities. Thyroid has been increased to forty grains a day. Differential count: Small mononuclear, 35.2 per cent.; large mononuclear, 11.6 per cent.; multinuclear, 48.8 per cent.; eosinophiles, 4.4 per cent.

Fifth day: Mental condition remains unchanged. Temperature, 99.4° F.; pulse, 112. Complaints of pain in the extremities. Rather restless at times. Quite well under the influence of thyroid, of which she is taking forty grains a day. Blood count: R. B. C., 5,656,000; W. B. C., 8,000. Differential count: Small mononuclear, 37.6 per cent.; large mononuclear, 12 per cent.; multinuclear, 45.2 per cent.; eosinophiles, 5.2 per cent.

Sixth day: General condition same as on day previous. Temperature, 99.4° F.; pulse, 128, weak and compressible. Thyroid has been increased to fifty grains a day. Differential count: Small mononuclear, 36 per cent.; large mononuclear, 12.2 per cent.; multinuclear, 46.4 per cent.; eosinophiles, 5.4 per cent.

Ninth day: No appreciable change in the mental condition. Still mildly depressed. Temperature, 99.2° F.; pulse, 125, weak, tension low. Thyroid was discontinued to-day. Blood count: R. B. C., 6,464,000; W. B. C., 6,000. Differential count: Small mononuclear, 34.4 per cent.; large mononuclear, 12.6 per cent.; multinuclear, 48.6 per cent.; eosinophiles, 4.4 per cent.

The patient's mental condition appeared to be in no wise affected by the course of treatment. The symptoms produced, however, were quite characteristic of the drug. It is of interest to note that the range of temperature in this case was much above the average noted in the other cases.

CASE IV.—P. B.—, female, aged forty-nine. A case of chronic melancholia of four years' duration, having the appearance of partial dementia. She was

quite dull, rarely ever speaking or taking any notice of anything. General health poor. Temperature, normal; pulse, 100. Physical examination revealed a well-marked insufficiency of the mitral valve. Preliminary blood count: R. B. C., 5,432,000; W. B. C., 8,200. Differential count: Small mononuclear, 10.8 per cent.; large mononuclear, 3.6 per cent.; multinuclear, 79.2 per cent.; eosinophiles, 6.4 per cent. Patient was put on desiccated thyroid, thirty grains a day, which was increased to forty grains on the second day.

Third day of treatment: No change whatever mentally. She is getting well under the influence of thyroid, of which forty grains are given a day. Temperature, 99° F.; skin flushed and moist; pulse, 105. Differential count: Small mononuclear, 20.2 per cent.; large mononuclear, 4 per cent.; multinuclear, 70.8 per cent.; eosinophiles, 5 per cent.

Sixth day: Taking forty grains a day. No marked change in mental state. Seems a little more irritable and talks more. Is thoroughly under the influence of the drug. Pulse, 120, weak and rapid; temperature, 99.2° F. Skin moist. Blood count: R. B. C., 5,312,000; W. B. C., 8,800. Differential count: Small mononuclear, 15.4 per cent.; large mononuclear, 4.2 per cent.; multinuclear, 79.2 per cent.; eosinophiles, 1.2 per cent.

Ninth day: Still taking thyroid, forty grains a day. Temperature, 99.8° F.; pulse, 132; tension very much diminished. No change in the mental state; still dull and stupid. Blood count: R. B. C., 5,288,000; W. B. C., 7,200. Differential count: Small mononuclear, 17 per cent.; large mononuclear, 7 per cent.; multinuclear, 75 per cent.; eosinophiles, 1 per cent.

A short time after the treatment was discontinued there was seen to be a very marked change in the mental condition of the patient. She began to take much more interest in her surroundings; would talk more, and her will power, which had been almost entirely abolished, began to reassert itself. There was no change of any consequence in her reasoning powers, however, and she soon drifted back into her apparently hopeless state.

CASE V.—P. V—, male, aged thirty. Had been insane three months. Emotional state very much exalted. Talks constantly in a disconnected manner. Has a general feeling of well-being. Physical condition fairly good. Temperature, normal; pulse, 85. Secretions appear to be normal. Preliminary blood count: R. B. C., 5,104,000; W. B. C., 11,100. Differential count: Small mononuclear, 17.2 per cent.; large mononuclear, 5 per cent.; multinuclear, 77.2 per cent.; eosinophiles, 0.6 per cent.

Thyroid extract, thirty grains, was given on the first day. It was increased to thirty-five grains on the second, and on the third day forty grains were given.

Third day of treatment: Somewhat more maniacal and quite irritable. Skin moist and flushed. Temperature reached 100.2° F. in the afternoon; pulse, 100. Blood count: R. B. C., 5,048,000; W. B. C., 4,400. Differential count: Small mononuclear, 29.6 per cent.; large mononuclear, 5.8 per cent.; multinuclear, 64.4 per cent.; eosinophiles, 0.2 per cent.

Fifth day: Patient more quiet but very emotional. Influence of thyroid on blood pressure quite apparent. Pulse, 102; temperature, 99.8° F. He is taking thyroid extract, forty-five grains a day. Differential count: Small mononuclear, 29.4 per cent.; large mononuclear, 5.8 per cent.; multinuclear, 64 per cent.; eosinophiles, 0.8 per cent.

Seventh day: Thoroughly impressed with the drug and apparently quite sick. Temperature same as on previous day; pulse, 110. Still rambling and disconnected in his talk. Blood count: R. B. C., 5,988,000; W. B. C., 6,600. Differential count: Small mono-

nuclear, 29.6 per cent.; large mononuclear, 5.6 per cent.; multinuclear, 63 per cent.; eosinophiles, 1.8 per cent.

Tenth day, fifteen hours after last dose of thyroid: Spent a comfortable night and is much more quiet this morning. Effect of the drug is still marked on the pulse. He has lost considerable flesh, although his appetite has been good. Blood count: R. B. C., 5,376,000; W. B. C., 5,800. Differential count: Small mononuclear, 27.2 per cent.; large mononuclear, 7.4 per cent.; multinuclear, 63.8 per cent.; eosinophiles, 1.6 per cent.

Ten days later the patient has improved very much physically and has about regained his former weight. There is also a very apparent change in his mental condition: he is much more quiet and his emotional state is only slightly exalted. Is still quite delusional, however, and incapable of reasoning. It was decided to give him another course of treatment similar to the first. He was accordingly put to bed again and another preliminary blood count made, which gave the following result: R. B. C., 5,368,000; W. B. C., 7,800. Differential count: Small mononuclear, 26.8 per cent.; large mononuclear, 6 per cent.; multinuclear, 66.4 per cent.; eosinophiles, 0.8 per cent. Patient put on thyroid extract again, thirty grains a day.

Third day of second course of treatment: Took thyroid, sixty grains. Pulse, 120; temperature, 99° F. No marked change mentally. Blood count: R. B. C., 5,338,000; W. B. C., 6,000. Differential count: Small mononuclear, 26.8 per cent.; large mononuclear, 7.4 per cent.; multinuclear, 65.4 per cent.; eosinophiles, 0.4 per cent.

Sixth day: Thyroid extract, sixty grains a day, is continued, and the patient is thoroughly under its influence. Temperature, 99.2° F.; pulse, 124, weak, and tension decidedly diminished. He is quiet but mildly exalted. Differential count: Small mononuclear, 26 per cent.; large mononuclear, 8.4 per cent.; multinuclear, 65.2 per cent.; eosinophiles, 0.4 per cent.

Eighth day: Treatment was discontinued. He has lost several pounds in weight and is quite weak. Continues to be quiet. Blood count: R. B. C., 5,296,000; W. B. C., 7,000. Differential count: Small mononuclear, 30.6 per cent.; large mononuclear, 9.8 per cent.; multinuclear, 58.8 per cent.; eosinophiles, 0.8 per cent.

Patient soon regained what he had lost physically. The improvement in his mental condition was continuous and very rapid. A note on the case made two weeks later says: "He now talks rationally and engages readily in conversation. Is no longer noisy and incoherent. Talks rationally on all subjects, and spends considerable of his time reading and seems to appreciate what he reads. He now sits up most of the day, but his pulse is still very rapid and not strong." Recovery was complete and has been permanent.

For the sake of brevity in the remaining cases only the preliminary count and another when well under the influence of the drug will be given. The numerical count of the red and white corpuscles is omitted in some cases where it was of no especial interest.

CASE VI.—I. H—, female, aged thirty-one. Chronic melancholia of a mild type, complicated with hysteria and hypochondria. Had been insane two years. Preliminary count: Small mononuclear, 33 per cent.; large mononuclear, 4.4 per cent.; multinuclear, 59.4 per cent.; eosinophiles, 3.2 per cent.

Large doses of thyroid extract were given and pushed until at the end of the fourth day the pulse was so feeble and rapid that it could hardly be counted. Patient complained of severe pains in various parts of the body, and could with difficulty be kept in bed.

This case was much more thoroughly impressed by the treatment than any of the others. Treatment had to be discontinued at the end of the fourth day. A differential count made then gave the following interesting result: Small mononuclear, 55.4 per cent.; large mononuclear, 9.2 per cent.; multinuclear, 34.6 per cent.; eosinophiles, 0.8 per cent.

The result in this case was entirely negative.

CASE VII.—J. G.—, male, aged sixty-two. Chronic melancholia of sixteen months' duration. Preliminary count: R. B. C., 5,008,000; W. B. C., 7,200. Differential count: Small mononuclear, 27.4 per cent.; large mononuclear, 9.2 per cent.; multinuclear, 55.4 per cent.; eosinophiles, 8 per cent.

Thyroid was pushed until a very decided effect was produced. Temperature at one time reached 100.4° F. A count made while patient was well under treatment gave: R. B. C., 5,240,000; W. B. C., 8,600. Differential count: Small mononuclear, 32.6 per cent.; large mononuclear, 16.8 per cent.; multinuclear, 47.2 per cent.; eosinophiles, 3.4.

No change was observed in his mental condition when treatment was discontinued, nor for several weeks thereafter. About one month after the course of thyroid he began to improve and clear up rapidly, and was discharged as recovered. Some doubt exists, however, as to whether or not his improvement was the result of the course of treatment, as recovery in his case was quite different from the others.

CASE VIII.—E. W.—, female, aged twenty. A mild type of mania of thirteen months' standing. Preliminary count: Small mononuclear, 24 per cent.; large mononuclear, 14 per cent.; multinuclear, 61 per cent.; eosinophiles, 1 per cent.

Differential count made on the seventh day of treatment: Small mononuclear, 31.2 per cent.; large mononuclear, 9.6 per cent.; multinuclear, 58.2 per cent.; eosinophiles, 1 per cent.

There was apparently no change whatever produced in her mental state.

CASE IX.—E. M.—, male, aged eighteen. A case of insanity of pubescence of eighteen months' duration. Preliminary count: Small mononuclear, 38.2 per cent.; large mononuclear, 6 per cent.; multinuclear, 54.4 per cent.; eosinophiles, 1.4 per cent.

Differential count made on the eighth day of treatment, when the patient was very thoroughly impressed with thyroid, resulted as follows: Small mononuclear, 51.6 per cent.; large mononuclear, 9.4 per cent.; multinuclear, 36.8 per cent.; eosinophiles, 2.2 per cent.

Result entirely negative, no change being produced.

CASE X.—C. C.—, male, aged thirty. A case of paresis in the first stage. Duration of disease, about four and one-half months. Symptoms well marked. Preliminary count: Small mononuclear, 19.8 per cent.; large mononuclear, 11.5 per cent.; multinuclear, 66.7 per cent.; eosinophiles, 2 per cent.

On the sixth day, when the effect of the treatment was very marked, a count was made, as follows: Small mononuclear, 28.2 per cent.; large mononuclear, 14.8 per cent.; multinuclear, 54.8 per cent.; eosinophiles, 2.2 per cent.

There was quite an apparent change in the patient's mental state when the thyroid was discontinued. He continued to improve until in the course of a few weeks he had lost delusions and talked rationally. Although four months have now elapsed since he was taken off treatment, there has been no return of his mental symptoms. Many of the physical signs of his disease have also disappeared. He is evidently enjoying a period of remission, such as is sometimes found in cases of paresis. This condition was undoubtedly produced by the course of thyroid.

From the examination made of these cases, as well as others, the study of which was more or less incom-

plete and therefore not reported, it appears that the number of red blood corpuscles is not materially affected by the administration of thyroid. In the stained specimens there is no deviation in the appearance of these cells from the normal.

There is also to be found no decided, constant, or characteristic change produced in the total number of white blood cells by the administration of this drug. In some cases the leucocytes are found to be increased, in others diminished in number, and my observation has been that the latter condition occurs more often. In no case have I seen anything approaching a leucocytosis nor any marked increase in the number of white corpuscles.

In the differential count, however, we see a very decided change produced in the relative number of the different varieties of leucocytes during a course of thyroid feeding. This change consists in the increase of the percentage of the small mononuclear cells or lymphocytes, and a corresponding diminution in the multinuclear neutrophils. By referring to the above tables, it will be seen that this condition exists in every case. It will also be seen that the increase in the lymphocytes bears a fairly regular ratio to the increase in the dose of the drug. It is quite reasonable to suppose, therefore, that this condition is a result produced by the administration of thyroid. This effect begins to be apparent on about the third day from the beginning of the course of treatment, and continues several days after it has been discontinued.

It is in the small mononuclear variety of lymphocytes that we see the only change in the appearance of the leucocytes in stained specimens. The lymphocytes in a specimen of blood taken from a patient thoroughly under the influence of thyroid extract are found to be much smaller, and the nucleus become stained more deeply than in a specimen taken from the same patient before treatment. This difference may be assumed to be the indication of the difference of the age of the cells. Uskow, of St. Petersburg, as the result of a prolonged and very close study of the blood, comes to the conclusion that the small lymphocytes with deeply stained nuclei are the youngest elements in the blood. This being the case, we are forced to the conclusion that the drug acts as a direct stimulant to those tissues of the body whose function is the production of the lymphocytes, namely, the lymphatic or adenoid tissues.

The blood of a patient who is taking large doses of thyroid extract also appears to undergo some chemical change. This is manifested by the very much more tardy manner in which the blood flows from a prick in the skin, making it at times difficult to obtain enough to fill the tubes of the hematocytometer without making quite a large puncture. The blood also coagulates more readily than under ordinary circumstances. What the nature of this chemical change is I cannot say, for, as previously stated, I have attempted no chemical analysis.

Now, let us see what bearing these cases may have upon the various theories advanced to account for the action of thyroid in mental disease.

Some writers upon the subject of thyroid therapy have advanced the idea that the good results obtained by it might be explained by the tonic line of treatment, with an increased appetite, more nourishing diet, etc., following the course of treatment. That this theory is entirely illogical and insufficient to explain the results obtained, will be apparent to all when we consider that the most decided improvement is often seen during the administration of the drug and before the tonics have been given. It has been so with some of my own cases.

Bruce, in his excellent article on this subject in the *Journal of Mental Science* for January, 1895, is inclined

to the opinion that it acts by producing a febrile state with its resulting reaction. I very much doubt that this is the true explanation; and, in fact, his paper itself would contradict the theory, for some of his patients made decided improvement in whom there had been a very slight if any rise of temperature. The highest temperature reported as due to thyroid feeding is no very marked deviation from the normal.

In Case I. it will be seen that the highest temperature recorded is 99.6° F., while the temperature before the patient was put on treatment was 99.2° F., an increase of less than 0.5° , and yet she began to improve immediately and made a rapid recovery.

In Case III. the temperature was normal at the preliminary examination, and registered 99.6° F. on the fourth day of treatment. In this patient there was absolutely no change in her mental state. The other cases will also show a similar lack of ratio between the increase of temperature and the mental change produced.

If the improvement noted in cases of insanity treated with thyroid extract is due simply to the febrile state produced, then why do we not have an equally high percentage of recoveries following intercurrent disease accompanied by high temperature? That such recoveries do occasionally occur is an undisputed fact, but, compared with the whole number of febrile diseases occurring among the insane, they can be considered only as interesting phenomena.

In the *Journal of Mental Science*, for October, 1895, Dr. Bruce reports sixty additional cases treated with thyroid. As a result of this work, he, while still adhering to the theory advanced in his first paper, comes to the further conclusions that thyroid is a direct cerebral stimulant and that the ingested thyroid supplies some material to the body which the gland is supplying in deficient quantities.

That this drug is a cerebral stimulant, direct or indirect, would certainly appear from its awakening the higher cerebral centres to functional activity in some cases of dementia in which the intellectual powers had been dormant for a long period of time.

That thyroid supplies some principle to the blood and thereby to the body is the most plausible explanation of its action. The cases cited show that it has a constant and decided effect upon the corpuscular elements of the blood by a stimulating action on the adenoid tissues. I am led to believe that it is by this action on the adenoid tissues that some principle is added to the organism which is being supplied in a deficient amount. It has been my observation that those patients do best on thyroid whose preliminary blood counts show a low percentage of lymphocytes. In Cases I. and V., in which recovery was complete and undoubtedly due to thyroid, it will be seen that the preliminary counts of lymphocytes were 18.4 per cent. and 17 per cent., respectively. Case X., which made the most marked improvement of any that did not entirely recover, had 19.8 per cent. of lymphocytes on preliminary count. The lowest percentage of lymphocytes found in any case before treatment was in Case IV., which had only 10.8 per cent. This patient, as will be seen, was partially demented, but still showed a decided mental change under treatment.

On the other hand, in Cases III., VI., VIII., and IX., whose preliminary counts of lymphocytes were respectively 24, 33, 24, and 38.2 per cent., absolutely no change was produced in their mental condition.

From these facts it is very plausible to suppose that in some forms of insanity there is a sluggish action of some of the tissues intimately connected with the function of hæmatisis, which tissues, being stimulated by a vigorous course of thyroid, elaborate and turn into the circulation some principle which has a beneficial action on the cerebral cortex.

While I thoroughly appreciate the fact that the number of cases studied has been too small to allow of a positive statement of the effect of this remedial agent, certain of the results obtained have occurred with such uniformity in every case that I am led to hope that by a more extended use and careful observation we may yet arrive at the true manner of its action.

In conclusion, I wish to acknowledge the valuable assistance of Dr. Thomas P. Prout, of the hospital staff, in the study of these cases.

HYPNOTISM AND SUGGESTION, WITH A CASE OF SPASMODIC STRICTURE OF THE OESOPHAGUS.¹

BY SAMUEL BROTHERS, PH.D., M.D.,
NEW YORK,

ATTENDING PHYSICIAN TO THE COLUMBUS DISPENSARY.

IN the following paper I use the terms hypnotism and suggestion collectively, but I do so because I believe it more practicable to speak of both together, since psychological suggestion merges imperceptibly into hypnotism and *vice versa*, and both probably affect the same portions of the cerebral mass, although with different degrees of intensity.

The words hypnotism and suggestion, in short, mean nothing more nor less than the processes which make a person believe what is not true, or what at the time he does not believe is true. This hypnotic state is explained by the fact that once a person having been made to think that he or she is asleep (for he may believe so when the eyes are not even shut), the phenomena of ordinary sleep will continue the natural time, during which the suggestions made will have profound effects. This is corroborated by the fact that persons can be hypnotized during natural sleep. Evidently, then, if we can prevent ourselves from shocking a sleeping person to wakefulness, and if at the same time we can induce the belief that we are the operators, the process is just the same. In natural sleep, a person has no operator, no supreme controller; in hypnotism he has: this is the difference. I have had subjects in the lethargic state who said after me that a long wooden rod was a pen, who wrote on my hand when I called it paper; and yet on opening their eyes they said they knew it was not true, but had to say so because I told them it was so. I have often said to waking patients, "Go to sleep again," and they have immediately fallen into slumber.

Webster defines hypnotism as follows: "Sleep, especially a kind of sleep or somnambulism said to be produced by means of animal magnetism; also a similar condition produced in persons of very delicate organizations, by gazing at a very bright object, as a metallic ball highly polished and strongly illuminated."

Dunghlison defines it under "Animal Magnetism" as "Mesmerism, Pathetism, Psycheism, Neurogamia, Biogamia, Biomagnetismus, Zoömagnetismus, Exoneurism, Anthropomagnetismus, Gargale, Gargalismus, Gargalus. Properties attributed to the influence of a particular principle, which has been compared to that which characterizes the magnet. It is supposed to be transmitted from one person to another, and to impress peculiar modifications on organic action, especially on that of the nerves. The discussions to which this strange belief has given rise are by no means terminated [1868]. There is no evidence whatever of the existence of such a fluid. Highly impressible persons can be thrown into a kind of hysteria or magnetic sleep and somnambulism, designated by Mr. Braid hypno-

¹ Read, in part, at a meeting of the Eastern Medical Society, February 7, 1896.

tism, neurohypnotism, and nervous sleep, and at times called, after him, Braidism; but farther than this, the efforts of the magnetizer cannot reach. It is a mode of action upon the nerves through the medium of the senses."

Suggestion, separate from hypnotism, seems to have received little notice in our medical literature. Dana gives, as synonyms of hypnotism the terms trance, artificial cerebral automatism, and electro-biology. Gradle gives the additional synonyms, provoked somnambulism and artificial trance, and he characterizes it as a state interfering with or entirely suspending the free will and judgment, together with readiness to obey the most unreasonable suggestions of others. Its effects, he says, resemble catatonia, etc., but differ from them in being transitory. Dana says, in defining hypnotism, that the state is one in which the phenomena allied to those of perturbed sleep (somnambulism) are exhibited, and considers it as a morbid mental state characterized by (1) perversion or suspension of consciousness; (2) abeyance of volition; (3) automatic response to commands or external impressions; and (4) intense concentration of the nervous force in some particular direction.

It seems to me that our whole lives must be inextricably bound up with psychical auto-suggestion (apart from hypnotism), since imitation seems to be the basis of its effects, and our every action seems to be the result of some impression, the outcome of certain imitative reminiscences.

What is the exact relation between the imitative faculty and "suggestion"? The child tries to imitate its guardian and its surroundings; and yet an advice or a command is followed or not, according as it is pleasing or the reverse. The same may be said of adults, although duty and civility modify the results. Has auto-suggestion anything to do with the urinary or other secretions, with defecation, with coition or with parturition? Is the attraction of the sexes hypnotic in nature? The thoughts are certainly concentrated in this condition. We might go further and ask if all animals, all plants, including even the single-celled animal or the bacterium—we might ask if all these are subject to the same force! Are all our actions the result of auto-suggestions? Is automatism unconscious suggestion? Are our reflex actions connected with hypnotism? We dream during sleep, and remember it after we awake. In the same way, the hypnotized subject dreams of some things which occur to him and not of others. Why should some impulses reach the centres of consciousness and memory and others not? We touch a hot stove and draw our finger away by a reflex action; then we first become conscious of what has happened. But the hypnotized subject does the same thing; tell him that he is sitting on a red hot stove and he not only jumps up, but he rubs himself! Is this merely automatic? A young girl follows the mental commands of her father to the letter, and yet not a word is spoken. Can the hypnotic be educated in certain directions? If an animal or a human being receives a great injury, he becomes unconscious, and we say that he is suffering from shock; but very often we get the evidences of so-called shock from a trivial injury, and even this may result in death. Now, what relation has this shock to mental suggestion? Has the subject's fright or fear of the consequences, or have the abhorrent actions of bystanders, brought on the condition? We know that the sudden receipt of very bad news, or similar circumstances, may throw a susceptible person into a cataleptic condition. Can some of our "heart failures" be attributed to the same cause? Can we make a person die by hypnosis? We can kill an animal by it!

A woman, even during (or after) the most difficult

version or instrumental delivery (with or without an anæsthetic), rarely becomes profoundly shocked, and a death from shock under such conditions is very rare.

In what way, again, do drugs act on the system? Why is one drug a cerebral excitant and another a depressant or hypnotic? How is it that sulphonal produces sleep on the second and even on the third day after it has been taken? Is there any hypnotic suggestion in this?

Dana claims that the understanding of hypnotism gives a key to all the cerebral automatic states. A certain portion of the cerebral cortex, he says, remains inactive during this process. This is caused by transitory inhibition of these functions. A steady monotonous impression is made on one of the senses to the exclusion of the others. This dulls the perception of the rest; during battle wounds are frequently not felt.

When an image is formed on one point of the retina, the sensibility of the other portions is reduced. If we fix our eyes on a luminous point, the surrounding objects become invisible. Suggestions are acted upon without the judgment based on the total evidence of the senses and on the remembrances of past experience. (It is thus, by the suggestive power of a lawyer, that a justice may be forced to take a wrong view of a case before him.)

Any slight irritation produces general spasms in strychnine poisoning, because the natural resistance to the nervous connections is diminished in the spinal cord. We must therefore infer that in hypnotism this resistance is increased and even blocked entirely in certain directions, but the opposite may also be made to occur.

Heidenhain and Bubnoff, on testing the galvanic excitability of the cortical motor centres in the dog, found it increased for a few seconds by every previous stimulus, even when the latter was too feeble to excite a muscular contraction. An electric stimulation of insufficient strength could also be rendered effectual by any slight irritation in the region of the muscles under the control of the centre experimented upon. Thus the excitability of the motor centre of the fore-leg could be distinctly raised by stroking the leg. On the other hand, the cortical excitability could be reduced in numerous ways. For instance, the contracture sometimes following stimulation of the corresponding centre could be checked by blowing on the leg. In short, they found that the excitability of the cortex was in anything but a stable condition, and that it fluctuated in either direction from remarkably slight causes.

The hypnotic anomalies of the motor system are shown by the researches of Tschiriew and Momsen, who have shown that the skeleton muscles are not in any state of tonic contraction until a muscle or its tendon is put on the stretch. When this occurs, as by tension of the antagonistic muscles, a gentle reflex tonic contraction is immediately produced. We get in this way the tendon reflex, a sudden jerk. This is increased often in the trance, showing hyper-excitability, and is also shown in the cataleptic condition. This exalted sensibility of the spinal centres must be attributed to the influence of the cerebral centres upon them. In the contractures the cortical motor centres are involved, for Munk and others have shown that these centres must be closely connected, if not identical with, those presiding over the "muscular sense," and the nerves of this sense—the tendons, aponeuroses, and other deep structures near the muscles, as well as the probable sensory nerves of the muscles—are the ones excited.

Locke, the poet, described the will as the "power to begin or forbear, continue or end the several actions

of our minds and motions of our body, barely by a thought or preference of the mind."

Dana, in the "Reference Handbook of the Medical Sciences," says that our reflexes may be classed as follows: (a) The simple reflexes of the spinal cord and medulla. (b) The dexterities: riding, playing, dancing, walking, playing on instruments and even suckling at birth (which is acquired without practice), and we might add a great many others to these; *i.e.*, even lecturing becomes in a degree automatic. These are called the machine-like (or automatic) actions; the centres are located in the lower ganglia and hinder part of the brain. (c) The third or highest system of reflexes: ideation, perception, etc. These include emotions of fear, etc., and ideas. Thus, a single frightful sight may give rise to prolonged feelings of terror.

In hypnotic conditions the entire phenomena are reflex, undisturbed by the will; these cause, no doubt, changes in the vascularity of the brain, with rapid breaking down of nerve tissue.

The peculiarity of hypnotism seems to be that, unlike the normal state, when a suggestion may be followed or not (according as it is received favorably or unfavorably), in this state it must be followed because the control of the will is absent. Patients will sometimes hesitate before following a command, but this must be ascribed rather to ignorance than to resistance; and yet, in the first stage, resistance is frequent. Can resistance be present in the more profound states of hypnotism? If a patient vomits in spite of commands to the contrary, can this be called resistance?

I will now describe a case of spasmodic stricture of the œsophagus, in which I tried the value of hypnotism. I must admit that the case is rather incomplete in some respects, but as this complaint is not specially noticed in our literature I undertake to describe it. Before beginning, though, I would like to say that the mass of my experiments have been on gynecological cases.

On August 27th of last year, Mr. A. C.—, aged thirty-one, called upon me with the following history: He had been ailing three months; had been married twelve years; no children; no specific history obtainable; said that his difficulty in deglutition became more and more profound as time progressed. At first he could eat solid food, but with difficulty; then he could swallow only pasty food, then liquids only, and finally even these were regurgitated. I failed to pass even the finest semi-elastic urethral catheter (they were the only ones at hand, but were made pliable in hot water, the wire staffs being discarded). He said: "I can take nothing since a long time but milk; anything like meat or bread first goes down and then comes up through my mouth and nose; sometimes when the bread is very soft a small crumb goes down; when I begin to swallow water it goes out again through the mouth and nose; and I have no appetite to eat."

This looked a little like hysteria, but still the previous history seemed to point clearly to an organic stricture of some kind. I made another attempt to pass a catheter, but failed even with a No. 9. The throat seemed to be very sensitive, and he gagged and vomited with each effort. He succeeded in swallowing a No. 9 soft-rubber bougie and also about eight inches of the stomach tube. I ordered boiled chopped meat and the following prescription:

R Hydrargyri chloridi corrosivi gr. $\frac{1}{12}$.
Potassii iodidi gr. x.
Syrupi sarsaparillæ compositæ 3 i.
M. S. Take the dose three times a day.

He said he could eat very soft spring chicken.

August 28th I passed a No. 11 catheter, and ordered

the mercury, etc., to be continued. He wanted to know if he should consult a professor. I gave him a note to Dr. Howard Lilienthal, in order to determine positively if there was any stricture.

On November 10th, three months later, I saw him again, when he related to me the following story: He had shown my note (addressed to Dr. Lilienthal) to a druggist who was a friend of his, and was advised by the latter to see another physician by whom he was treated for a time, but was finally sent to the German Hospital.

At this time again, although I could not pass the smallest semi-elastic catheter, he could swallow, of his own accord, the large soft-rubber stomach tube. The case was therefore plainly a spasmodic stricture of the œsophagus.

I ordered:

R Spiritus ætheris compositi,
Tincturæ valerianæ ammoniatæ āā 3 ss.
Misturæ asafœtidæ,
Aquæ āā 3 ss.

This he was directed to take every four hours, and also beef tea or kumys.

November 11th there seemed to be some gastric irritability, so I ordered:

R Sodii bicarbonatis gr. x.
Magnesiæ ponderosæ gr. v.
Sacchari lactis gr. v.
Olei anisi gtt. ss.

The stomach tube was not retained so well as the day before, although the smaller semi-elastic ones passed and were retained, as were the smaller soft ones.

November 12th he said he felt better, but had had ten passages the previous day and one on this day. I made the No. 11 semi-elastic catheter pass by distracting his attention; this was done by inducing him try to pull his hands apart. He then swallowed the No. 13 without trouble. I ordered Hoffman's anodyne, valerian, and asafœtida in doses of ten drops of each, *t. i. d.*, after meals, in a wineglass of water.

On November 18th the valerian mixture was continued, but the powders were changed a little by adding five grains of saccharated pepsin in place of the heavy magnesia; barley, farina, and milk were ordered.

On the 20th he said that "the food stops and then goes down with a gurgling sound." I gave him potassium bromide in half-drachm doses, with syrup, citric acid, and water. I tried a soft-rubber tube larger than the stomach-tube, but saw no signs of blood stains on the tube and desisted.

On November 22d I passed a flexible steel tube with fangs that could be spread apart by pressing the opposite end; this was withdrawn open. I ordered raw chopped meat.

November 24th he complained that he gagged after eating raw meat and had to put his finger in his throat, which caused part of the meat to be vomited. I tried to pass a No. 9 wooden rod, but had to desist for fear of doing harm. I ordered the compound spirit of ether and valerian in twenty-drop doses, *t. i. d.*, and bromide at night only.

On December 5th I decided to hypnotize him, as he seemed to be tiring of his prospects. I told him to look in my eyes, and made passes across his forehead and down his face for about ten minutes, suggesting sleep all the time. He showed a tendency to smile when I began, but he finally fell off into a deep state of hypnotism. Before treating him I made a few experiments. Under the suggestion that his chair was a hot stove, he jumped up in a natural manner, rubbing his trousers. He showed natural excitement when I told him that a child was falling out of a window: he

went on all fours and trotted about at my suggestion that he was a horse. Impersonating a cat for me, he caught a pencil in a natural way, taking it for a rat. He was a Russian Pole and understood very little English. He imagined himself an actor on the Hebrew stage, even recognizing his friends in the audience; he spoke in the German-Jewish jargon and sang in the same strain. Then he was made to believe that the theatre was an English one, and he tried to imitate Booth to the best of his ability; French, of course, he did not understand, but my limited vocabulary of the language he imitated admirably. He believed himself in heaven or in sheol, according to my desire, but showed that he had only his ordinary impressions about them. He played the piano harmoniously, under the impression that he was Paderewski, using every finger and at my demand playing slow or fast; he had probably never touched a piano before. He shot an imaginary bird, thought it was winter or summer, and felt correspondingly hot or cold. He found a needle, although I had to direct his movements, as he seemed unaware of things in his way and would undoubtedly have fallen over everything obstructing him. He sat down and played with imaginary toys when I told him he was a baby, or acted like an old woman or giddy female at my desire. He impersonated Corbett at my request and did well with Fitzsimmons. His limbs became rigid or mobile in any part or in any position; or some became mobile and others rigid at the same time, as when he thought he was a pump, the rigid left upper extremity being worked like a pump handle. Then, again, a clean needle was passed through the loose skin of his hand, while he exhibited a pleased expression. While he believed a part immovable, the greatest force would hardly overcome the rigidity, yet a single suggestion made it lax again.

Now I began to make use of the therapeutic properties of hypnotism. I made passes over the œsophagus, telling him that he would be able, when he awoke, to eat food of any kind without any difficulty. In order to emphasize this, I gave him imaginary food, which he appeared to eat and drink with ease. After awakening him, which I accomplished only after considerable clapping of hands, combined with suggestions for him to wake, I asked him what had happened, and he said "I ate zwieback."

December 6th I hypnotized him more readily this time and told him that zwieback and everything else would go down without any trouble. I made ascending "passes" and told him to wake up. After a time he came out of the condition, opening his eyes with a start.

December 11th I invited a number of neighboring physicians in his presence, but he seemed to have got frightened, and would not enter the hypnotic state under any consideration; he pleaded that he was not at all sleepy. I ordered Hoffman's anodyne and valerian in forty-drop doses. I ordered also fifteen drops of saturated solution of the bromide every four hours. Perhaps the gaslight or the comparative want of quiet disturbed him also.

December 12th he said that "farina goes down but milk sticks and is spit out again; the pill goes down without water but not with water." Since the first séance he seemed to be suffering from some outside depressing influence, as shown by his actions and apparent fear, and also from the fact that solicitous friends appeared on two occasions to ask about him. I failed to hypnotize him.

In the evening of December 14th he was again hypnotized. From this out he was hypnotized regularly until he became delinquent and finally disappeared altogether. At one time I ordered him mentally when he failed to appear punctually, and he

came; but this may have been merely a coincidence. At another time I learned that he was taken to Brownsville to prevent him from coming, and finally, after hypnotizing him in the presence of his wife, it seemed to have a still worse effect and he was kept away altogether. I ordered him by postal card a week later, but his wife appeared instead, evidently determined to keep him away at all hazards.

Let us see what other authorities have to say on the subject.

Gradle makes the following statement: "When a susceptible person stares at some bright object, like a button, without being disturbed otherwise, or when the forehead is stroked by an operator, the subject appears to become drowsy in the course of a few moments. . . . The first time it may require a persistence of some fifteen minutes or more. Gradually the object appears indistinct to the subject, his eyelids droop, and he seems to fall asleep. Occasionally more of a dazed condition occurs than actual sleep."

The subject may be awakened by shaking him. The reaction of the pupil to light is usually not abolished although the subject may be sightless. The person indicates that he sees, but does not interpret correctly what he sees. The sense of hearing may or may not be interfered with. The taste is usually, the smell sometimes, abolished. Carpenter mentions a young woman who found the owner of a glove, in a company of sixty, by the smell. Very frequently subjects have the ability to perform delicate movements without the sight. They have been made to write with the eyes bandaged. They may row or ride horseback, or dance. They will recall incidents in their past which they do not remember in their normal state.

Gradle says further that a certain number of patients will recall some of their experiences, but as if in a dream. The muscles can be thrown into steady contraction by pressure on them or their nerves, with the finger or any instrument, as precisely as by electricity. Some of these contractures may persist, in hysterical patients, even after the subject's return to the normal condition, but by a gentle rubbing of the antagonistic muscles the contractures can readily be stopped. In another phase, the cataleptic, the entire body presents the wax-like flexibility of catalepsy. Charcot found three stages in hysterical patients, lethargy, catalepsy, and somnambulism. The lethargic state is produced by staring or by gentle pressure on the eyeballs. It is characterized by mental stupor and hyperexcitability of the motor system. Contractures produced on one side of the body can be transferred to the corresponding parts opposite, by holding a magnet near the part to be affected. This effect is prevented by making the limb anæmic with an Esmarch bandage. If we apply pressure to muscles through the bandage, the contracture will be sure to follow its removal; even while the bandage is applied, the contracture can be transferred back again by the magnet.

The lethargy gives way to the cataleptic state on opening the eyes, and especially on exposing them to a strong light, or by suddenly producing a loud noise. (Most of my subjects have been awakened by these means.) The features of this state are plasticity of the muscles and of the mind, the latter revealing itself by the miens and gestures of the subject on suggesting any train of thought. By keeping open only one eye this side will be cataleptic, but the other will remain lethargic. The somnambulist state may then be induced by gentle rubbing of the forehead. In this latter state the delusions, hallucinations, and imitative tendencies predominate. In those not afflicted with hysteria, these separate stages are not evi-

dent. The derangements of circulation, respiration, and other involuntary functions are merely the result of the intense emotions experienced. These "stages" give the erroneous impression that they are transferable only by following the directions given, whereas, as a matter of fact, these changes are more subservient to "suggestion" than to anything else.

Dana says that by cultivation almost any one can train himself to enter the state at will: he further states that the person who has been hypnotized at first sits or lies quietly in the position he assumed during the manipulations of the operator. Some of my subjects have fallen back when asleep; one of them stood with difficulty, he seemed to be so sound asleep, and, although I suggested repeatedly that he was not sleepy, he suddenly fell (fortunately in a rocking-chair), the shock waking him up. No notable changes, Dana says, occur in the pulse, respiration, temperature, pupils, or skin. Some increase in the cerebral blood supply, though, is said to be present.

The patient will now, at your command, talk, walk, run, gesticulate, assume expressions of fright, anger or joy. Outside of these he hears, sees, smells, tastes, and feels nothing. He can be made cataleptic, somnambulistic, or paralytic. This state is termed somnambulistic trance. If left to himself, he gradually sinks into a deep sleep, from which he can with difficulty be roused. After rarely more than one or two hours he awakens as from an ordinary slumber; this state is called trance coma or lethargic hypnotism. The three forms of the French writers are hardly possible, according to Dana. Sensitive subjects can be thrown at once into any one of these states (including the cataleptic).

The best method of inducing this state, he says, is to hold for five or ten minutes some bright object at a distance of from six to eight inches from the eyes, and a little above the horizontal plane of vision. (I sometimes induce it by making them look at the quicksilver in a thermometer bulb while facing a bright gaslight and simultaneously looking into their eyes.) It is self-induced by fixing the attention rigorously upon some object, says Dana, as in the ecstatic states of the saints and the nirvana of the Buddhists, as well as the states of some clairvoyants, spiritualistic preachers, and "mind healers," and it enters also into rational therapeutics. He refers undoubtedly to the use of suggestion, independent of hypnotism, for he adds, that "the capacity of the human mind for hypnotism or semi-hypnotic states is, therefore, a most curious and important fact." After a time even a word of command is sufficient to hypnotize a subject. The practice is injurious, he claims, tending to exhaust the nervous force and weaken the will. Faith-healing institutes, Dana thinks, are more pernicious than ginmills. This seems to indicate that it would be better to take up this matter in its incipiency and make some attempt to obtain legislation before it has gone too far.

The subject is dehypnotized by command or pass of the hand, or by any impression that the patient expects for the purpose. Under the spell they have been observed to have a diminution of the spinal reflexes and a muscular hyperexcitability. They sometimes show a most extraordinary exaltation of the visual, auditory, or other special sense, although the statement of Luys that medicines in sealed vials can be made to act is hardly credible.

To distinguish malingering of hypnotism, which sometimes is done for purposes of injury or crime, the following rules are laid down: (1) Careful examination of the subject by an expert is necessary to note the general actions. (2) The muscular hyperexcitability is tested by percussing the motor points. (3) The alleged anæsthesia is tested by unexpected burn-

ing, or pinching, or injury. (4) Testing the tetanic rigidity by the revolving tambour. In conscious states a tremor soon appears when the hand is kept extended at arm's length. (5) The subject may be tested with eyeglasses and other apparatus to determine anæsthesia of the special senses.

It is very aggravating at times to have a subject almost completely under the influence and then have him awakened by some disturbance. When the subject shows a tremor of the eyelids or makes motions as of swallowing saliva, or sighs, or motions with the hands, or wipes tears from the eyes, in spite of continued efforts, he will not be hypnotized at this séance beyond the first (the lethargic state). He will talk to you and tell you anything you ask of him, hearing and knowing meanwhile everything that is going on around him. In spite of this, however, suggestion will have a marked effect, although occasionally it requires some persistence. For instance, once in a while a patient will insist for some time that she does not experience what you tell her. In the end, however, you will generally succeed. I have often been successful in hypnotizing even when the subjects plainly did not wish to be hypnotized, and I have given marked relief to numbers by suggestion without asking them to sleep at all.

One advantage of direct suggestion, apart from hypnotism, is that it can be used *ad libitum*, as it produces no apprehension on the part of the patient.

Some cases of profound hysteria in males are very obstinate toward the influence of hypnotism. These are especially the patients who feign almost every symptom known. A large percentage of subjects can (with sufficient patience) be brought under the influence. Liébault states that in one thousand and four persons, twenty-seven could not be hypnotized, three hundred and thirty-five became sleepy, while all the rest passed into the trance. While hysterical females yield more readily than any others, Heidenhain noticed that strong muscular development is also favorable to its production. Infants and idiots could not be hypnotized by him.

Dana says that about one in every ten or fifteen adults is susceptible. It is said that the "magicians" in India hypnotize a whole audience, and I have demonstrated the possibility of this by hypnotizing a whole group without moving from the centre of the room. In my experience in dispensary practice, the large majority do not get beyond the first stage (although I have succeeded better of late). The worst drawback which I have had to contend with in my experiments is the great distrust which the attempt usually engenders, although I do better now by grouping subjects together. The foreign Hebrew element, especially, is extraordinarily superstitious. One young man was mortally afraid that I was going to use a knife on him when he was asleep. Another patient, a middle-aged woman, seemed to be afraid that I had evil intentions.

I became acquainted with hypnotism while a chemist nearly fifteen years ago. Dr. Parrish at that time was the first I met who understood the subject practically, he having taken a course of instruction from two professional lecturers. I made no practical use of it, however, until recently.

It has been frequently claimed that by fixing the attention upon a person unseen, he or she will be attracted by it. I concentrated my attention recently upon a subject separated from me by two glass doors. She had seen me pass in from the street to the vestibule and apparently thought I went on upstairs. Although she turned and looked at me, I have little doubt that she became aware of my presence and saw me staring at her.

If in a theatre, you concentrate your attention on

a person in front of you, he or she will often turn around; but this is caused by the fact that other people, noticing your unusual actions, draw his or her attention to you. We all know that there is a language in looks and actions. Bend your head forward suddenly in a car and look at something—all the passengers will look after you. Your actions have said plainer than words, "There is something unusual there," and they all want to see what it is. It must be remembered, when people see things without looking at them, that although the macula lutea with its fovea centralis retinae is most powerful in sight-giving properties, still the surrounding parts of the retina can also produce mental impressions, and, considering that we have two eyes, this gives us a very large range of vision; although looking straight ahead, we can see objects on both sides of our heads. We have all been the subject of attention in assemblages at times, and yet have felt no particular attraction; that was because we are accustomed to it. In other instances we have felt embarrassed, and have tried therefore to avoid such congregations.

The old method of hypnotism, says Dr. Luys, was to cause the subject to look one steadily in the eye, while the operator's hands were continuously passed about his head. To be successful by this method, he says, the subject must feel that he is going to be hypnotized and must not offer the slightest mental objection. (My experience does not agree with this.) The principle of his hypnotizing machine is a constantly moving, glittering surface.

The great requisite for successful hypnotization is unbounded self-confidence and fearlessness. If you are afraid that the patient may laugh at you, you will never succeed. I have hypnotized the very patients who were forced to smile at first. I was asked recently by a man of apparently strong will-power if I thought I could hypnotize him. "Why," said I, "you would be the easiest of subjects!" Still I did not believe so myself at the time, and yet the effects of my answer could have been observed in the patient's subsequent demeanor.

Dr. Abbot Combes, who was a student under Charcot, claims that every advanced physician nowadays should know how to hypnotize. He takes a hen and bends the neck to one side and then draws up one of the wings over the head. Holding her in this position, he whirls her around twice and then sets her down. With eyes wide open, she sits perfectly rigid; placed upon her back, she makes no effort to regain her upright position; when one of the wings is spread out, it remains there. This is the second or cataleptic stage, in which she remains for several minutes. Other birds of smaller varieties are handled in the same way, with similar results.

A young man is seated by him in a chair and he doctor points his finger at him, keeping it about five inches away from the subject's head and on a level with his eyes. The young man's eyes droop and in a very few seconds he is in the first stage (somnolency). By pushing open the eyelids (and pressing slightly upon the eyeballs?) the second stage, or cataleptic condition, is reached. Placed in any position, no matter how uncomfortable or ridiculous, the subject remains there. When needles are introduced into the flesh, the man never winces; he is deprived of all feeling. A minor surgical operation, as the amputation of a finger, could be performed without the least difficulty, but a major operation, as that of removing the arm, would produce such a shock to the nerves as to bring the subject out of the trance.

By stroking the middle of the forehead with the finger he produces the third and last stage, hypnotic suggestion. (He thus calls the stages by the more appropriate terms, somnolence, catalepsy, and sugges-

tion—or still better terms would be insomnolence, catalepsy, and servility.) All the stages are frequently present at the same time, in varying proportions. "He will remain under my control," says the doctor, "unless I suggest that he is under the control of some one else or awaken him: if I place him under the control of any other person, I have no control over him until the governing party suggests again that he should be under my control." The subject is burned with cold iron, and drinks water, thinking it is milk. If a woman has hysteria, he suggests that she will not have another attack until she sees him again: the effect is generally very satisfactory. The length of time the influence lasts depends upon the number of times she has been hypnotized, how susceptible she is to the influence, and what her capability for receiving the suggestion is; as a general thing it lasts for from two to four weeks. The patient is awakened by blowing in his or her face. When a disease is long-continued, says Dr. Combes, as in functional epilepsy of from fifteen to twenty years' standing, it is hardly possible to cure it in this way. In alcoholism, you can keep a man from drinking by suggestion, but it will not reduce the inflammation of the brain cells in delirium tremens. When patients complain of pain as the result of an operation accomplished two years previously, with no foundation for such complaint, they are cured in this way. Alcoholics are told that if they drink in the future it will make them sick, and it does generally make them vomit; this suggestion lasts for two or three weeks. Sometimes we say, "Don't go into a saloon." The same is done for the smoking-habit, when necessary. If they complain of headache after continued hypnotism, the treatment is usually suspended for a while.

The doctor does not believe that a man who is thoroughly moral and principled could be induced to commit a crime, nor could a virtuous woman, according to him, be made to surrender herself. (Can they resist without the presence of the will?) Still, he admits that subjects have engaged in antics which would have made them feel disgraced in the normal state. It is claimed that a subject would forget to do a criminal act as soon as he had left the presence of the operator.

In producing the hypnotic state artificially in man, Dana says, his attention is first fixed upon some particular object, as a bit of glass, which is held slightly above the level of vision, so as to put the ocular muscles upon a certain strain; after a few minutes, in sensitive subjects, the nervous force seems to lose its equilibrium, and to concentrate itself in one particular direction; the whole mental life of the subject is narrowed into one field. The equilibrium of nervous force being once overturned, it remains unstable, and can be turned in one direction or another, at the will of the operator. The subject is told that he is a murderer and must die, and he is overpowered with fear and remorse. The hypnotic is to all intents and purposes anæsthetic (unconscious to feeling) and blind and deaf to everything except an expected suggestion from the operator, who is the only link between him and the external world at this time. The concentration of his nervous force upon some particular function, such as that of sight, hearing, or touch, exalts these senses, so that vision is clearer, hearing more acute, and the touch more sensitive.

Certain persons of a highly sensitive, nervous temperament, are liable to spontaneous attacks called trance, which is nothing more than a day somnambulism. These individuals are generally hysterical, and their attacks may be accompanied by or complicated with catalepsy, ecstacy, or various other hysterical phenomena. In some cases this is said to be congenital, any excitement of the brain producing a spell; in others

it may be acquired, after the subject has been mesmerized. A case is reported of a patient with chronic periodical tic douloureux who fell in a state of "somniloquence" after each attack; her religious eloquence was a modern illustration of the prophecies of the priests of the Delphic oracle. If the hypnotic is left alone, his condition passes after a few hours into true sleep. Those periodically hypnotized can recall in one séance what occurred at a previous one.

The slighter degrees of hypnotism resemble profound reverie or abstraction; the absorbed reverie of the student, however, is different from the absorbed contemplation of the hypnotic. The student is constructing and building under voluntary direction; the latter is going automatically over old ground.

Gradle claims that hypnotism can be more easily produced in functionally nervous patients than in healthy subjects. The patient, he says, stares at a bright object, in a quiet room, or listens to a monotonous noise like the ticking of a clock; or having his forehead or nape of the neck warmed by means of the hands of another person, or the radiant heat from warm plates held at a short distance, will answer the same purpose in some instances.

It is true that the action of a mesmerizer who has had experience in producing this state facilitates its occurrence, but the popular idea that it requires a mesmerizing operator is not fully accurate. This state can be produced more readily the oftener it is accomplished. Susceptible and credulous subjects have been mesmerized at a stated time, even in the absence of the operator. A direct mesmeric influence is an unsupported myth, not bearing rigid criticism. The touch of a magnet may be used for producing hypnotism, but there is no other connection between them. Usually certain muscles are kept on a strain in its induction.

Braid's method of treatment by hypnotism was to direct the attention during the trance upon the parts depressed in function and to direct it from the organs supposed to be in a state of excitement.

He suggested its use for surgical operations, and quotes Esdaile as having performed three hundred operations under it. Wiebe obtained encouraging results in cases of hysterical spasms and tremors and in hysterical hemianæsthesia; also in non-hysterical neuralgia. Voisin obtained good results in the management of insanity. He found it useful to calm excitement, to feed obstreperous patients, and to elicit their history. Pritzel put a girl into a trance during her first labor; the birth was accomplished in one and one-quarter hours without pain; she recollected nothing about it.

Its therapeutic indications are, then, prolonged pain, as neuralgia, or the passage of a calculus; if other methods are available it is not prudent to take the chance of failure (though this is not so essential now, since its use is becoming popularly understood). For surgical anæsthesia it is too uncertain. A good field is hysteria, somnambulism, catalepsy, ecstasy, and some forms of insanity. Since some individuals complain of mental stupor and physical lassitude after hypnotization, it is probably not safe to repeat such experiments often (its effects cannot therefore be altogether imaginary).

It must not be forgotten that a good deal of time is unconsciously expended on these cases, and herein may lie part of its value. A young woman thus describes her own cure from neuralgia by pure suggestion. She was shown into a pretty room and placed in an easy chair; a silk cushion was placed under her head, a footstool supported her feet. The attendant lighted a small spirit lamp under a vaporizer and put a dainty bib under her chin. With a soft sponge moistened in warm water and some sweet-smelling material, the masseur made the application, and man-

ipulated the aching spot with firm, cool fingers. Vigorously, but gently, she rubbed the surface with the soft, practised cushions of her finger tips. This brought the blood to the surface with a peculiar sensation of refreshment. After this treatment some fragrant cream, medicinally treated, was rubbed in. The cream that did not penetrate was washed off with cold perfumed water, to prevent taking cold from exposed pores. The final step was a mild application of electricity by means of a soft kid pad over the face. After three-quarters of an hour of this enforced leisure and dallying with creams and perfumes, a week-old neuralgia was chased away.

Hewitt and Sims, in their treatise on the "Diseases of Women," devote four chapters to the subject of the hystero-neuroses, which are very interesting in this connection.

Chambers' Encyclopedia, edition of 1883, gives the following description of the subject: "From the Greek *hypnos*, sleep, a term invented by the late Mr. Braid, of Manchester, to designate certain phenomena of the nervous system which in many respects resemble those which are induced by animal magnetism, but which clearly arise from the physical and psychical condition of the patient, and not from any emanation proceeding from others. The following are his directions for inducing the phenomena and especially the peculiar sleep-like condition of hypnotism: Take a silver lancet case or other bright object, and hold it between the fingers of the left hand, about a foot from the eyes of the person experimented on, in such a position above the forehead as to produce the greatest strain on the eyes compatible with a steady fixed stare at the object. The patient must be directed to rivet his mind on the object at which he is gazing. His pupils will first contract, but soon dilate considerably, and if, after they are well dilated, the first and second fingers of the operator's right hand, extended and a little separated, are carried from the object toward the eyes, the eyelids will most probably close with a vibratory motion. After ten or fifteen seconds have elapsed, it will be found that the patient retains his arms and legs in any position in which the operator places them. It will also be found that all the special senses, excepting sight, are at first extremely exalted, as also are the muscular sense and the sensibility of heat and cold. But after a time the exaltation of function is followed by a state of depression far greater than the torpor of natural sleep. The patient is now thoroughly hypnotized. The rigidity of the muscles and the profound torpor of the nervous system may be instantly removed, and an opposite condition induced by directing a current of air against the muscles which we wish to render limber or the organ we wish to excite to action: and then by mere repose the senses will speedily regain their original condition. If a current of air directed against the face is not sufficient to arouse the patient, pressure and friction should be applied to the eyelids, and the arm or leg sharply struck with the open hand.

"From the careful analysis of a large number of experiments, Mr. Braid is led to the conclusion that by a continued fixation of the mental and visual eye upon the subject, with absolute repose of the body and general quietude, a feeling of stupor supervenes, which renders the patient liable to be readily affected in the manner already described. As the experiment succeeds with the blind, he considers that it is not so much the optic as the sentient, motor, and sympathetic nerves, and the mind, through which the impression is made."

We see from the above that hypnotism was considered at this time to be entirely distinct from mesmerism or animal magnetism, which is described in a separate article, being defined as "a supposed

influence or emanation by means of which one person can act upon another, producing wonderful effects upon his body, and controlling his actions and thoughts. It was fancied to have some analogy to the magnetism of the lodestone," the article goes on to say, and hence its name. "Electro-biology, odylism, table-turning, spirit-rapping, table-talking, and spiritualism have been classed as only modifications of the same phenomena. The art of inducing the magnetic state, as practised by its discoverer, Mesmer, involved the use of apparatus—the *baquet* or magnetic tub, iron rods, etc., but the more common means have been passes made by the hands of the magnetizer from the head of the subject (or patient) downward, or simply making him fix his eyes on the operator.

"He then generally feels a creeping sensation stealing over the surface, and shortly falls into the mesmeric sleep—a state more or less resembling somnambulism or sleep-walking.

"About one person in ten is found capable of being thus affected to a greater or less extent.

"While in this state, the functions of the body are liable to be much affected; the pulsations of the heart and the respirations are quickened or retarded and the secretions altered, and that chiefly at the will of the operator. [It might thus be useful in dropsy.] One liquid tastes as the other, and is hot or cold, sweet or bitter, as the subject is told."

According to this mesmeric theory, the nervous energy of the operator has overpowered that of the subject, as a powerful magnet does a weak one, and the two are *en rapport*, as it is termed. In some cases, the mesmeric trance assumes the form of clairvoyance. The author goes on to say that "it has been clearly established, however, that the notion of a force of any kind whatever, proceeding in such cases from a person or from a magnetizing apparatus, is a delusion."

Where it is to be looked for was indicated, though not followed up, as early as 1785, in the report of the commissioners, one of whom was Franklin, appointed by the king of France to examine these pretensions of Mesmer. They reported that "on blindfolding those who seemed to be most susceptible to the influence, all its ordinary effects were produced when nothing was done to them but when they imagined that they were magnetized, while none of its effects were produced when they were really magnetized but imagined that nothing was done; that when brought under a magnetized tree [one of Mesmer's modes of operating] nothing happened if the subjects of the experiment thought they were at a distance from the tree, while they were immediately thrown into convulsions if they believed they were near the tree although really at a distance from it; and that, consequently, the effects actually produced were purely imaginary."

Braid traces the whole thing to the brain of the subject acted on by suggestion, a principle long known to psychologists, though never made so prominent as it ought to be. In reviewing the subject Dr. Carpenter traces the operation of this principle (*Quarterly Review* for September, 1853) through the most ordinary actions, which no one thinks wonderful, up to the most miraculous of the so-called "spiritual" manifestations.

A train of thought is internal suggestion (auto-suggestion), but impressions from without originate and modify these trains, constituting external suggestion (direct suggestion). These phenomena enable us to explain the physical excitement attendant on "revivals," "camp meetings," etc.

No wish of the mesmerizer, or of any other person, was ever known to affect the "subject," until it was conveyed to him by voice or otherwise (unless we accept the cases recently reported). If he is more subject to the will of the operator, this is because he was

impressed with that idea. He is thus made to lose and recover memory, or even his own identity.

The manifestations of table turning, such of them as are genuine, are explained by the operation of expectant attention. A number of individuals sit around a table with their hands resting on it, having the idea in their minds that it will or may move, the direction of the expected movement being also agreed upon. Accordingly, if none of the party are very sceptical, it generally does move after a time, all declaring, and in perfect good faith, that they did not press upon it. And yet it has been proved by a contrivance of Faraday that there always is pressure, though without the will or consciousness of the performers.

The wonders related by believers are to be received with suspicion, but without accusing the relators of bad faith (because they are suffering from the effects of auto-suggestion).

The mysterious indications of the divining rod and of an oscillating body, such as a ring suspended from the finger, are all to be accounted for by unintentional muscular movements.

Beard and Rockwell, in their treatise on "Nervous Exhaustion," 1888, say that "morbid states of the nervous system which we call trance, but which are popularly known as hypnotism, somnambulism, catalepsy, all being special varieties of the special generic condition, trance, is one of the interesting, though perhaps not most frequent or the most serious of the sequels of neurasthenia."

Neurasthenia is not, by any means, they say, the most common of the exciting causes of this state. In the middle ages, among many wild, savage, and semi-barbarous races, trance existed, and in modern times it has spread as a mental contagion, even among persons who have great strength of constitution, or at least who have but very little of the nerve element in them.

Trance of this variety, in its psychical form, is found to-day among certain classes of people, but the majority of the cases of trance, among our better classes, are seen in women who have entered the state through the doors of neurasthenia. Our so-called starving girls, with their ecstasies and visions, are oftentimes neurasthenic for years before they develop trance phenomena.

The time may be near at hand when we shall be able to observe these mental phenomena by actual sight. We can photograph the skeleton through the body already, and who knows but with the aid of multiple instantaneous chromo-micro-photography we shall think nothing some day of looking at the brain-cells in action, in natural colors?

In connection with general hypnotism, another question presents itself, and that is this: In view of the fact that this state has a tendency to depress the mental faculties, should parents, guardians or teachers be allowed to load the minds of children with fairy stories or with mythological religion? Since religious mania takes such a prominent place in our works on mental disease, it seems only natural that all but real historical religion should be excluded from the studies and the libraries of children. Would it not be more advisable to teach them psychology and its laws in an appropriate form?

Although Spitzka, 1889, in his "Insanity," has nothing to say on hypnotism or its allied conditions, I abstract the following paragraph as being of interest in this connection.

"In private practice, melancholia, particularly of the lighter grades, is very common, and is not unfrequently treated as neurasthenia—whatever that may or may not be—and dyspepsia, and, thanks to the self-limiting tendency of the lighter forms of the psychosis, it is frequently cured on either theory."

It has been said that every genius is to a certain extent, insane. I believe myself that it would be truer to say that every person who concentrates his mental faculties in one particular direction, is more or less hypnotic, at greater or smaller intervals, and for varying lengths of time.

Brown in his "Medical Diagnosis," 1890, speaks of somnolence, among other causes, as being the result of a "natural aptitude for sleep possessed by persons of a lethargic temperament."

Howe, in his treatise on "Excessive Venery," 1889, under "Mental Emotions," cites: "'A powerful imagination will create that which it imagines' in a short space of time." A new mental creation, without a basis in fact, obscures and distorts that which is real.

The records of hospital and private practice show that there is little limit to the power of this influence in creating organic changes, when the nervous system of the patient is abnormally sensitive. (This being the case, why not reverse the emotions by opposing impressions?) He goes on to describe a case, while he was an interne at Bellevue Hospital, in which a hysterical patient developed peritonitis with tympanites and later an apparent mastitis with swelling of the breast, through being placed in proximity with patients suffering from these affections; twelve months after, to his great surprise, he found the same person, who was supposed by the staff to be dying from inflammatory softening of the brain.

Hamilton, in his "Medical Jurisprudence," says that it is very rare that trance can be given as an excuse for the active commission of a crime. It might be possible to account for the ignorance of an individual by the fact of his being unconscious or being thrown into a state of suspended consciousness through fright or a strong moral impression.

A case is related of a theft claimed to have been committed in the mesmerized state. In court the man appeared to be in a sound sleep and did not understand the questions put to him by the magistrate. It was stated that he fell in this state after his arrest, although before this he had given an account of himself. No medical aid could arouse him. Even his brother, who was a lecturer on mesmerism, could not arouse him, although he answered questions readily. The brother said that he was susceptible for a long time, and that on one occasion he became violent and had to be restrained. The prisoner subsequently recovered, after going for several days without food or drink. He was sentenced to fine and imprisonment. An act of violence, Hamilton says, had it been committed, would have suggested criminal irresponsibility, but theft implies personal benefit. The verdict was probably a righteous one.

Dana (*Medical Annual*, 1889) states that the doctrines of Bernheim are far more correct than those of Charcot. The operator talks to the subject in a firm voice, assuring him that he will go to sleep in a short time, telling him to make no resistance—that his sleep will be natural, that nothing will be done to worry or fatigue him, that he will dream pleasant dreams, that he will wake up feeling better; then that he is feeling drowsy, objects seem confused, the lids are falling, they are closed—in a moment more the patient goes off to sleep. This is the persuasive or suggestive method. It requires from five to fifteen minutes. The method is applicable to neuralgias, neurasthenias, hysterical, convulsive, and paralytic troubles, alcoholic and morphine habits, amenorrhœa, rheumatic troubles, etc.

Tuckey (*Medical Annual*, 1890) says that Liébault hit upon the value of suggestion in the hypnotic state. Intelligent artisans he found to be the best subjects, especially when tired out by the day's work. Anæmic and phthisical patients, and adoles-

cents of both sexes, are also easily hypnotized. Even if the patient has been frequently hypnotized, mental emotion, such as fear, will prevent it succeeding.

Liébault finds in 100—uninfluenced, 5; slightly influenced, 15; sleepers, 65; somnambulists, 15. The same proportion is found among the phlegmatic Dutch and many somnambulists are found among the Swiss. A larger proportion of English is uninfluenced (two per cent.), and there are fewer somnambulists (eight per cent.), but this may depend upon coincidence. The condition is analogous to but differs from sleep; in sleep imagination has full play and runs riot in dreams, whereas in hypnotism it can be controlled, so as to influence even the heart and circulation, the vasomotor centres, and intestinal and uterine secretions.

In hysterical paralysis, aphonia and amaurosis, neurasthenia, spinal irritation, railway spine, brain fag, sleeplessness, functional derangements of the genito-urinary organs, such as ovarian irritation, vaginismus, impotence, nocturnal enuresis, headaches of nearly all kinds, even migraine or neuralgias, and even in gouty sciatica in old men it is useful.

In menstrual difficulties, whether dysmenorrhœa, amenorrhœa, or menorrhagia, not only when dependent on functional causes, but even sometimes when there is structural change, e.g., subinvolution; in occupation neuroses, as writer's cramp (for which hypnotism is often combined with massage); in painful local affections, as cramp, torticollis, and lumbago; in some cases of epilepsy, and especially in hysterio-epilepsy, it will modify the attacks even in the traumatic forms.

In nervous dyspepsia, colic, and some forms of constipation and diarrhœa, it may be employed; also in the sympathetic and functional troubles of organic disease, as palpitation and sleeplessness in cardiac disease, or constipation and lightning pains in locomotor ataxia. As an anæsthetic during labor it may sometimes be useful, as well as to relieve after-pains. In hypochondriasis and in melancholia it may be tried, but it is difficult to influence patients with mental disease. In acute mania it may succeed, but great patience is necessary. It effects wonders in dipsomania, the morphine habit, masturbation, and other vices; these cases should be kept under observation for twelve months to prevent a relapse.

The rules laid down by Beaunais are as follows: (1) Never hypnotize except with the patient's free consent and if necessary that of friends. (2) Never make any experiment without the knowledge and consent of the patient. (3) Never operate except in the presence of a third person. (I consider these rules altogether too stringent.)

93 MADISON STREET.

Syphilis in Infants and Young Children.—If "snuffles" are present, irrigation with boric-acid or thymol solutions, or bichloride of mercury (1 to 1,000), or with a one or two per cent. aqueous solution of ichthyol, will be suitable. For mucous patches, mild solutions of nitrate of silver, or of mercuric chloride are of benefit, while for the condylomata, cleanliness, dryness, the use of nitrate of silver, or of calomel in powder form, five to twenty per cent., are indicated. Fissures at the angles of the mouth I have seen much benefited by balsam of Peru, painted on in full strength, ichthyol ointment, ten per cent., or by touching with the nitrate-of-silver stick.—ELLIOT, *New Orleans Medical and Surgical Journal*, May, 1896.

Disinfection of Hands.—It seems conclusive that the great enemy to all surgery, the hand of the operator, is best disinfected as first taught in Baltimore, by the use of solutions of permanganate of potassium and oxalic acid.—HENRY O. MARCY.

WHAT IS THE BEST OPERATIVE PROCEDURE FOR RETRODEVIATIONS OF THE UTERUS?

By AUGUSTIN H. GOELET, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE.

In considering the treatment of retrodeviations of the uterus, the maintaining cause of the displacement must be borne in mind, and the existence or absence of an associated disease of the adnexa must be determined. We may divide these cases into three classes:

The first class will include those in which the organ is freely movable and will admit of replacement, but in which the displacement recurs upon the removal of the support which replaces it. In these cases a metritis and an endometritis or their result are the maintaining cause, the relaxed uterine supports being a secondary consideration, at this time, though in the beginning they may have occupied a more prominent etiological position.

The second class will include those cases in which, in addition to a metritis and an endometritis, adhesions or surrounding exudation bind the fundus of the organ immovably in Douglas' cul-de-sac. In these cases a previous or perhaps an existing inflammation of the adnexa is the cause of the fixation, though moderate fixation from adhesions may occur independently of inflammation of the appendages.

In the third class may be included those movable retrodeviations complicated by prolapsed, enlarged, and sensitive ovaries, which preclude the use of a vaginal support for maintaining the uterus in a corrected position.

Now let us consider the objections to and the disadvantages of some of the operations which have been devised for these displacements, and see if they are necessary or justifiable, and, if so, when they are indicated.

The Alexander operation is the least objectionable, since it seeks to restore the organ to a normal position in the pelvis. Its chief disadvantages are: (1) the time which the operation requires; (2) the doubt about finding the ligaments sufficiently strong in their long overstretched and atrophied condition to bear the strain to be put upon them; (3) the prolonged convalescence necessary before the shortened ligaments can be regarded sufficiently strong to support the uterus; (4) the risk of hernia; (5) the cicatrices which may become the seat of keloid. (Several cases of this kind have come under my observation and have proven very disagreeable and intractable.)

The shortened ligaments do not interfere seriously with subsequent pregnancies, though in two cases which came under my observation considerable pain in the region of the wounds and shortened ligaments was experienced in the later months of pregnancy.

The actual indications for this operation may, in my opinion, be regarded as very circumscribed. It would seem to be particularly applicable to the cases belonging to the third class mentioned above, viz., when a movable retrodeviation is associated with prolapsed, enlarged, and sensitive ovaries which cannot bear the pressure of vaginal support, but which are not sufficiently diseased to require removal. In ordinary movable retrodisplacements when the operation is supposed to be indicated, it is unnecessary. This operation may be done for fixed retrodisplacements, the adhesions being previously broken up through a vaginal incision opening Douglas' pouch. But when the adhesions are extensive I believe it will be more satisfactory to separate them from above through an opening in the abdominal wall, and when they are

not firm or extensive Alexander's operation is unnecessary, as the malposition can be satisfactorily overcome by a procedure to be described farther on.

Ventrofixation as ordinarily done may hardly be regarded a justifiable operation. It draws the uterus up out of the pelvis and fixes it in an abnormal position. These patients sometimes suffer considerable pain resulting from the strained and unnatural position of the organ. This unnatural position must prove a complication to subsequent pregnancies. Several unfavorable cases have been reported.

The suspension operation of Kelly, in which the uterus is suspended by its posterior face from the anterior abdominal wall and in which it is not fixed permanently, but is merely suspended and eventually recedes to the distance of about an inch and swings in an easy position of ante flexion, is certainly less objectionable and is more rational. It should, however, be limited to those cases of firmly fixed retrodisplacements associated with diseased adnexa which require removal. It is unnecessary in movable retrodeviations. When the uterus is firmly adherent, I believe it is safer and more satisfactory to open the abdomen and break up the adhesions from above than from below through a vaginal incision.

I cannot see that intraperitoneal shortening of the round ligaments possesses any advantage over suspensio uteri, and the operation consumes more time.

Vaginal fixation should not, in my opinion, be regarded as a justifiable operation. It substitutes an exceedingly awkward fixed anteversion for a movable posterior displacement. The complications during labor following this operation which have been reported should be sufficient to condemn it. It has already been abandoned by its originator, Mackenrodt.

It will be admitted, I think, that if the intra-abdominal pressure can be brought to bear permanently upon the posterior face of the uterus, it will be held anteverted. It must, likewise, be admitted that if the maintaining cause of the displacement when the organ is or has been made movable (the metritis and endometritis) be at the same time overcome, a positive cure must result. This will, of course, presuppose the possibility of a cure of such disease of the uterus and also retraction of the relaxed suspensory ligaments.

I believe that ninety per cent. of all the cases of movable retrodeviations are amenable to a very simple procedure which I have employed with success for the past ten or twelve years. I have employed it also in cases of moderate fixation when the adhesions could be separated by manipulations through the vagina and the abdomen without opening the peritoneal cavity, the patient being under anesthesia to secure absolute relaxation. This should, of course, be undertaken only when we can be certain that there are no pus accumulations in the pelvis. When the adnexa are incurably diseased, it is wiser to open the abdomen, and, after removing such diseased structures as is necessary, suspend the uterus from the anterior abdominal wall.

The procedure to which I refer aims at a cure of the metritis and endometritis, which may be regarded as the most prominent etiological factors in maintaining movable displacements. It consists of careful dilatation of the canal, thorough curettage of the cavity, followed by frequent irrigation to promote and hasten the formation of a healthy endometrium. Immediately following the operation of dilatation and curettage, a glass drainage tube is inserted, which in the case of flexion, acts as a splint, holds the organ straight, and converts it into a version. It will then be an easy matter to adjust vaginal tampons of iodoform gauze so as to throw the uterus into a position of anteversion and hold it there. It is very necessary to adjust these tampons daily and keep the patient confined to bed.

At the same time the tube is removed and cleansed, the cavity irrigated, and it is reapplied.

I have found that if this is kept up for a week, in the majority of cases a vaginal pessary may then be adjusted to hold the uterus in an anterior position without the aid of the glass tube in the canal, even in old flexions with considerable induration of the walls. In some cases, however, it will be necessary to retain the tube in the uterus for a few days longer after the vaginal pessary has been inserted. When it is found that the pessary will maintain the organ in an anterior position, and the tube can be dispensed with, the patient is permitted to get up. She must, however, be kept under close observation for a time, to make sure that the pessary is maintaining a correct position; and the cavity should be irrigated from time to time until a healthy condition of the endometrium has been restored. Measures to promote retraction of the relaxed uterine supports (faradization, for instance) should likewise be employed. This will very materially aid in bringing about a cure, which I consider is secured when the vaginal pessary can be dispensed with.

This procedure brings about rapid softening of the uterine walls and favors the retention of the uterus in a normal position by the vaginal support.

In cases of retroversion, when the organ is in a state of subinvolution in the soft stage of metritis, after the dilatation and curettage the cavity is packed with iodoform gauze for a week, to stimulate contraction and depletion. The gauze, however, is removed and renewed every twenty-four hours, the cavity being freely irrigated at the same time. Vaginal tampons are inserted to hold the uterus in a position of anteversion, and at the end of a week a vaginal pessary is inserted and the patient is permitted to get up.

The only disadvantage of this procedure is the time and trouble which the after-treatment necessitates in order to accomplish a satisfactory result, but this is more than counterbalanced, it seems to me, by its absolute safety and the restoration of the organ to a normal position in which its function is not interfered with. As compared with shortening of the round ligaments, which is so often done for movable displacements, the chief advantage in favor of this procedure is the shorter confinement to bed and the quicker convalescence. It is also, I believe, more certain and more rational.

To recapitulate, Alexander's operation is not necessary in movable retrodeviations unless they are complicated by prolapsed, enlarged, and sensitive ovaries which do not require removal.

Ventrofixation substitutes a fixed abnormal position, for some reasons more objectionable than the original displacement.

Suspension of the uterus from the anterior abdominal wall is indicated for firmly fixed retrodeviations, especially when the adnexa are diseased, and it yields a very satisfactory result.

Intraperitoneal shortening of the round ligaments possesses no advantages over suspensio uteri.

Vaginal fixation is never indicated and should be discouraged.

The operation of dilatation with curettage, and the subsequent use of a glass drainage splint for the correction of the flexion, is indicated in the large majority of movable retrodeviations, and is more rational, since it restores a normal position of the organ without submitting the patient to any risk, and does not entail prolonged confinement to bed.

The Horseless Carriage is now used by French country physicians.

NOTES FROM THE LABORATORY AND DISPENSING-COUNTER.

By AUGUST DRESCHER, A.B., PH.G.,

NEWARK, N. J.,

CHEMIST TO THE NEW JERSEY STATE BOARD OF HEALTH.

Dispensing Calomel with Sugar of Milk.—For years all of us have dispensed calomel, together with "cane sugar," in the form of powders, and no fault may have ever been found with this combination. Within the last few years it has been found by many of our physicians to be necessary to follow the "progressive line"—that is, to change the "old-fashioned" cane sugar to milk sugar, in the case of admixture with calomel, and even with more delicate and more easily decomposable chemicals. "Milk-sugar fame" came from abroad, and we here naturally ape European fashion, whether rightly or wrongly. In my experience calomel and milk sugar, safely ensconced in a good powder paper, as is the common practice among pharmacists, will not keep so long as a mixture of "cane sugar" and calomel, without showing signs of decomposition (turning gray).

This is generally not noticed, because of the large quantity of sugar of milk present, the excess hiding the discoloration; but when, as in my store it is often the case, small amounts of sugar of milk are wanted with calomel, so that the powder can be placed dry upon the tongue or into the mouth of a small child, the metamorphosis of the calomel can be easily noticed before the administration of the dose.

Calomel with Sodium Bicarbonate.—Quite recently a graduate of pharmacy asked me to account for the "black streaks" in the mortar in which he had been triturating calomel with sodium bicarbonate. He knew well enough that sodium carbonate, heated with certain metallic salts, effected reduction, but of its effect in the cold or that of the bicarbonate he had no idea.

The same thing happens to us almost every day, when we triturate calomel with sodium bicarbonate in various quantities, to form "tablets" (this new curse of pharmacy). The reaction is simply this:

and the tablets turn gray. In mixing powders we had the chance of pulverizing finely each ingredient in the mortar by itself, and then mixing them all together upon paper with a spoon or spatula; but tablets must be moistened, even if only with alcohol and a little water, in order to bring the particles more nearly together. The alcohol cannot be supposed to act in the case, conceding to it all its powers of affinity.

Incidentally, I would here say that among the authorities on chemistry there ought not to be a difference of opinion as to the formula for calomel. Even good authorities on chemistry have quoted HgCl . The majority is, it appears to me, in favor of Hg_2Cl_2 . Logical reasoning suggests at a glance the latter to be the more correct. For, when we construct the formula of a compound, we naturally first of all look at the oxides capable of formation. Upon their formulae we generally base the whole series of possibly formable salts. Thus we have: $\text{Hg}'_2\text{O}$ = mercurous oxide, and $\text{Hg}''\text{O}$ = mercuric oxide, showing Hg to be both a monad as well as a dyad. In accordance, the formula of calomel must be:

Were we to adopt the formula of HgCl , we would not account for the oxide, except that we accepted

HgO₂, involving a fraction of a unit, contrary to our custom at present.

Copper Arsenite (Scheele's green).—H₃' (AsO₃)''' (arsenious acid), being a tribasic acid, admits of the formation of three series of salts by saturation with monadic basic radicals. With copper arsenite (in tablets) the writer has had an experience quite recently, and the salt was prepared and the tablets were served, all made in his own laboratory, in less than one hour's time. The article in question is well known to chemists, but there are many druggists or pharmacists who do not know it as a drug. It was made in a hurry in the following manner (as chemists apply the Cu test for arsenic), taking proper care to have stoichiometric equilibrium established for this purpose. The reactions:

The atomic weights were used in round numbers: As, 75; S, 32; O, 16; Cu, 63.

Since then I have selected another relatively more productive progress, which, however, does not produce real "Scheele's green" but saturated Cu₃(AsO₃)₂, which physicians, it seems, prefer. It can be made just as the other salt, by applying more CuSO₄. Thus:

For the production of the CuHAsO₃ a great deal of skill is required, as the liquid out of which it is to be precipitated must be critically neutral, the least excess of either acid or base acting as a direct solvent, resulting in loss of yield.

In closing, I would remind my readers of the difference between copper arsenite and "Paris green" of the trade. Paris green, French green, Schweinfurth green, are all mixtures of Scheele's green with more or less copper subcarbonate or subacetate, such color-shades as may be required for technical purposes.

Progress of Medical Science.

Puerperal Pulmonary Thrombosis.—At a recent meeting of the Edinburgh Obstetrical Society, a report of which is published in *The Lancet*, Dr. J. Lomond Lackie read a paper on "Puerperal Pulmonary Thrombosis," with an illustrative case. The patient was a strong, healthy primipara, aged twenty-six. She enjoyed good health during pregnancy, but during the last few weeks of gestation suffered from considerable anasarca of the legs; there was no trace of albuminuria. The labor was easy and there was an unusually small quantity of blood during labor and after the separation of the placenta. The puerperium was practically normal. On the twelfth day she walked from the bed to a chair, a distance of twelve feet, and as she reached the chair she exclaimed she was dying, complained of shortness of breath, and collapsed on the floor. Her face became livid, she struggled for breath, and speedily became unconscious. Dr. Lackie saw her within six minutes of the onset, when she was dying; the extreme lividity of the face was very marked. Restoratives and ether were used, but she died two minutes later. On post-mortem examination the uterus was found to be normal in size, the fundus being just above the brim of the pelvis, and it was somewhat flabby. The cavity was normal and aseptic. There was no indication of clotting in the veins of the pelvis or in the femoral veins, at least in their upper part. All the organs of the body seemed healthy; but

on opening the pulmonary artery there was found a thrombus, white, dense, and fibrinous, adherent to especially one side of the vessel, and extending into both branches and their ramifications for some distance. On the surface of this clot there was more recently coagulated blood. The right ventricle of the heart was also occupied by a recent dark purple clot. There were absolutely no premonitory symptoms to lead one to anticipate this result. The small amount of blood lost during labor was unusual, as this condition seems to occur more easily in those weakened and anæmic from hemorrhage. A few cases of recovery have been recorded. Ammonia and diffusible stimulants can be given, and, if life is prolonged, inhalation of oxygen may be of service.

Bismuth Naphtholate.—Dr. Edmond Chaumier regards beta-naphthol as the best of all intestinal antiseptics, although it has a disagreeable taste. It can be prescribed as a mixture with some bismuth salt or as a combination—beta-naphthol bismuth, which has no burning taste. The last in the alimentary canal decomposes, breaking up into naphthol and bismuth oxide. It is a gray powder, slightly aromatic, and contains 26.5 per cent. of beta-naphthol. In infantile diarrhœa the fetid stools lose their odor, the watery evacuations become thicker, and the green color disappears under the influence of this drug. It can be administered in two to five per cent. solution in quince syrup, of which the dose is one teaspoonful. In diarrhœas of larger children and of adults the remedy acts quickly, and with a sufficient dose—seventy-five to one hundred and fifty grains in wafers—they disappear within one or two days. If the pain is severe opium may be added. For both infants and adults it is well to continue the remedy for some time after the diarrhœa has stopped. The diarrhœa of the tuberculous is of great importance, because it interferes with nutrition, emaciates the patients, causes them to lose strength, and prevents the administration of proper remedies. The remedy has been used as well in the temporary diarrhœa, which in a few days will undo the benefits of several months, and in the chronic form, which is almost continuous and constitutes the principal lesion. In the first case the creosote carbonate, the only active and safe drug against tuberculosis, should be stopped and naphthol bismuth given, not only during the disease, but for several days after. In the chronic cases, when the diarrhœa has existed for several months or years, the abdomen is painful upon pressure and the appetite is very much diminished. After prolonged use of the drug these symptoms disappear and the creosote can again be administered. In typhoid fever (two cases) the intestinal disinfection was perfect, the tongue was always clean and moist, and the convalescence was brief.—*American Journal of the Medical Sciences*.

Appendicitis.—(1) All cases do not require operation; on the contrary, some cases are best treated without operation. (2) In cases requiring operations the appendix should be removed; (a) when there is no pus; (b) when an endo-appendiceal abscess is present; (c) as a rule, when there is a peri-appendiceal abscess that requires drainage through the general abdominal cavity; and (d) when there is general peritonitis without adhesions, with the exceptions noted. (3) A simple incision should be made and drainage provided in cases with circumscribed abscess, when this can be done without opening the healthy peritoneal cavity. An exception should be made to this rule in cases in which the removal of the appendix will not add to the gravity of the operation.—PORTER, *Medical News*, September 14, 1895, p. 290.

New York, August 29, 1896.

RECTAL EXAMINATIONS IN THE DIAGNOSIS OF ABDOMINAL DISEASE IN CHILDREN.

It has been truly said that more mistakes in diagnosis are made from failure of observation than from lack of knowledge or misinterpretation of facts. This is more especially true in the case of children and infants, in whom subjective manifestations are not to be depended upon even when intelligently conveyed. It is for this reason that any addition to our diagnostic resources will be hailed with satisfaction, and in such a light must be viewed the recommendations contained in a communication dealing with the subject of rectal exploration in the diagnosis of abdominal disease in children presented by Dr. George Carpenter at a meeting of the East Sussex Medico-Chirurgical Society (*The British Gynecological Journal*, May, 1896). His first experience in this connection, he relates, was acquired in the discovery by a senior colleague of a myeloid sarcoma of the anterior surface of the sacrum in a little girl who had long suffered from constipation. "Not satisfied with firing off all the drugs in and out of the pharmacopœia," this practical man determined to use the "hands and brain that nature had provided him with" and "proceeded to make a rectal examination." Influenced by this example, Dr. Carpenter began the systematic employment of rectal examination in the diagnosis of abdominal and other obscure disease in children. He cites a number of illustrative cases in which this mode of procedure rendered the utmost service. Thus, in the case of a small boy, three years old, presenting an umbilical fistula and enlargement of the mesenteric glands, rectal examination disclosed the existence of a pea-sized nodule in the position of the prostate gland and extending from it slight enlargement of the seminal vesicles on either side. A probe introduced into the sinus reached the prostatic enlargement, and it was concluded that a tuberculous abscess of the prostate had burrowed along the urachus and had found vent at the umbilicus.

In the diagnosis of tuberculous peritonitis digital examination through the rectum, in conjunction with bimanual palpation, is capable of yielding conclusive information, disclosing, especially in the early stages, a lumpiness due to matting of the intestines. An anæsthetic facilitates the exploration, but is not al-

ways absolutely necessary. With the patient's legs well drawn up, the thighs flexed on the abdomen, the pelvis raised on a cushion, the left hand of the examiner on the abdomen and the right index finger in the rectum, the right side of the abdomen can be explored. By reversing the hands the left side can be examined up to a level depending upon the length of the examining finger and the size of the child. If the intra-abdominal tissues that can be included between the finger in the rectum and those upon the abdominal wall are inconsiderable in thickness, peritonitis can be safely excluded. If, however, the thickness of the tissues is considerable, it is probable that the peritoneal coat of the bowel is thickened by lymph. Bimanual palpation is capable of disclosing not only intestinal matting, but also peritonitis without definite abdominal nodules, or a thin plaque of omental thickening perhaps coarsely granular. At the same time glandular involvement if present can be appreciated. The partially filled bladder must not be mistaken for a peritonitic exudate, and conversely a localized collection of pus or other fluid may simulate a distended bladder. The use of a catheter will aid in the differentiation. If doubt exist as between fecal lumps on the one hand and glandular enlargement or intestinal matting on the other, an enema will make the distinction. Intestines involved in peritonitis tend to move *en masse* when pressed upon, and do not yield so quickly to the fingers as in health. Small empty and constricted coils of intestine may yield a sensation similar to that of inflammatory thickening of the intestine, but the mistake is not likely to happen more than once and will be avoided if such a condition is borne in mind.

Rectal examination may thus not only give valuable positive information in a doubtful abdominal case, but it may throw a totally different light upon a case of abdominal disease which may appear to admit of but one interpretation. In the case of a child presenting broncho-pneumonia and an abdominal tumor following whooping-cough it was feared that tuberculous peritonitis existed; but rectal examination, with bimanual palpation, disclosed the tumor to be a horseshoe kidney. Malignant disease, and especially sarcoma, may give rise to nodules which can sometimes be detected only by rectal examination or by bimanual palpation. Intussusception, likewise, may be discoverable only by this means. Simple inflammatory affections of the peritoneum may simulate tuberculous or other lesions by the formation of abdominal tumors. Abdominal abscesses are often tuberculous, but occasionally they have a different origin, sometimes starting from the vermiform appendix, rarely from an antecedent pneumonia or following typhoid fever, and are sometimes of unknown origin. A not common variety of abdominal tuberculosis is attended with involvement of the mesenteric glands, in the absence of other complications. Even less commonly the intestines are surrounded by tuberculous false membrane, which can be readily stripped off. The invaginated portion in case of intussusception conveys to the examining finger a sensation like that of the os uteri advanced in pregnancy. With a knowledge of this fact the differen-

tiation from tuberculous peritonitis may sometimes be made.

In children the sacrum as well as the rectum is almost straight. The infantile bladder is egg-shaped, with the larger end downward, and as the pelvis is shallow it is almost entirely an abdominal organ. As soon, however, as the child begins to walk, the bladder sinks more into the pelvis, though even then its attachments are so loose that it readily rises wholly into the abdominal cavity when distended or otherwise displaced—a feature observed almost until the period of puberty. The child's uterus consists almost entirely of cervix and it lies in the upper part of the pelvis. At birth the ovaries have descended as far as the brim of the true pelvis, but in children a few weeks old they are found close to the external iliac arteries at the side of the pelvis. The ovaries are for the most part elongate oval in shape; occasionally more or less rounded organs are found. The falciform or utero-sacral ligament forms a guide to the oviduct. The former pursues a sickle-shaped course surrounding the rectum, being attached behind to the sacrum and in front to the lower part of the cervix. Using this structure as a guide, the tubes and ovaries, which are on a higher plane, can be readily manipulated between the exploring finger and the bony wall of the pelvis, or bimanually. The ureters can be examined at the same time. It is sometimes possible to detect in the ovaries the small cysts or dropsical ovisacs not infrequently found post mortem. The uterus, on account of its mobility, is not readily detected in this way, but if the bladder be emptied any marked abnormality can be appreciated by bimanual palpation. In young children the uterus can be rolled between the finger and the symphysis pubis, and its contour made out with ease. Ovaries and tubes may be displaced into the inguinal and crural openings. A case is on record of a child three months old in whom an ovary and oviduct that had descended into the inguinal canal were removed. Tuberculosis of oviducts, uterus, and ovaries is extremely rare in children. Inflammatory disorders of the tubes and ovaries in children have received but little, if any, attention. A case is on record of a little girl in whom symptoms of pelvic peritonitis developed in the sequence of an attack of gonorrhœa. Salpingo-oöphoritis sometimes complicates vulvo-vaginitis in children. The inflammation may subside into latency and be revived at the period of puberty.

With the knowledge thus far gained, as indicated in the foregoing delineation, an agency of practical value is placed in the hands of the clinician in the employment of rectal examination in the diagnosis of abdominal and other disease in children.

Fat Witness Fees.—At the Carlisle meeting of the British Medical Association it was stated that Sir Thomas Stocker received \$1,000, Sir Dyce Duckworth \$600, Mr. Ward Cousins \$300, and Dr. Bateman \$200 for their services in testifying in behalf of the editor of the *Association Journal* during the suit brought against him by Dr. Kingsbury.

THE TREATMENT OF ACNE.

THE lesion in acne is an inflammation of the sebaceous glands and adjacent tissues. All writers upon the subject agree that the causes are to be divided into three classes: the overproduction of sebum, impediments to the escape of the sebum, and irritation of the gland by foreign matters, such as pyogenic organisms from outside or drugs eliminated through the glands. These three general causes represent the fundamental factors in causing the disease. We find that a further analysis of the etiology, however, such as is given in an article on the subject of acne by Dr. R. A. McDonnell (*Yale Medical Journal*), increases the number of causes to eighteen or twenty; and one concludes from a study of the list that acne can be produced by almost anything, from indigestion to a state of exalted self-consciousness.

The article by Dr. McDonnell gives a *résumé* of some of the modern methods of treating this troublesome disorder. In the acutely suppurating forms, incision, so as to allow free bleeding, followed by washing with antiseptics and the application of aristol powder is indicated. In perhaps the more numerous class of suppurating cases, in which the suppuration is slight and the number of pustules very great, incision is impracticable, and the application of some preparation which will produce desquamation is recommended. A preparation containing ten parts of beta naphthol, fifty of sulphur, twenty of green soap, and twenty of vaseline is recommended. This is to be spread thickly over the affected surface, allowed to remain on for about three-quarters of an hour, and then wiped off. This application is made every day in the evening, for five days. As a result, the surface desquamates in thin epidermal scales. A soothing paste is then applied every evening and allowed to remain all night. The well-known Lassar paste, composed of salicylic acid, oxide of zinc, starch, and vaseline, is recommended for this. In the milder, non-suppurating cases, in which firm red papules abound, the application of the Lassar salicylic paste is often sufficient, so far as external medication is concerned. Return of the trouble is prevented by the use of cleansing lotions, which keep the gland ducts open. For this purpose a five-per-cent. resorcin soap is recommended. But the ordinary measures of bathing in very hot water and thorough friction of the skin are often efficient. Some dermatologists use ichthyol soap and others advise soap linament, some antiseptic being incorporated with it. Reinold prescribes, for example, bathing the face night and morning with hot water applied on a sponge previously kept in a one-per-cent. sublimate solution. The face is rubbed for several nights with black potash soap, the latter being left on till morning. The face is then washed with warm water and dusted with starch. After a few days emollient applications, such as boric-acid solutions or glycerin and water with sulphur, are applied.

The internal measures necessarily depend very much upon the age and condition of health of the patient. Acne in a period of adolescence is due to the physiological stimulation of the sebaceous glands,

produced by the sudden increase in the growth of the hair. But this is often aggravated, as is well known, by reflexes, anæmia, and sexual neuroses. Dr. McDonnell thinks that, as a routine prescription, the pill of aloin, belladonna, and strychnine is to be recommended. The aloin, undoubtedly, is the only one of these constituents that does any particular good. A good many people find that they cannot eat certain foods without the development of acne. Oatmeal, cheese, butter, bananas, and candy are some of the substances which affect the sebaceous glands unfavorably. Internally, arsenic may be given also, and, empirically, ichthyol, in doses of five to seven grains, and sulphide of calcium are recommended. The latter drug had, at one time, much vogue, but its reputation has hardly been sustained.

The number of remedies, external and internal, which have been recommended and which can be advantageously employed in the treatment of acne is very great, and it is most important, after all, therefore, that the physician discover the cause underlying each case of acne, in order that he may treat it intelligently and prevent a recurrence.

News of the Week.

Dr. C. H. Hughes, of St. Louis, has been appointed honorary president of the section of neurology and psychiatry at the Pan-American Medical Congress. All who intend to present papers in this section are requested to communicate with Dr. Hughes.

Cattle Plague in Jamaica.—A very serious plague has broken out among the herds of cattle in the island of Jamaica, and the government has sent for Mr. Williams, the cattle expert of Scotland, to study the disease and, if possible, to prevent its further ravages.

Picric Acid is recommended by Thiery, of Paris, in the treatment of burns. He immerses the part for five minutes in a solution of the strength of one part to sixty of water and then wraps the part in wadding, protecting it, if excoriated, by iodoform gauze.

Just an Employee.—Among the widely advertised attractions of a new shop in this city is to be a hospital for the benefit of any of the shoppers who may be taken ill. There will be a resident physician, and it is announced that his services will be gratuitously rendered to any of the patrons of the establishment, "just as those of any other employee of the house."

Roentgen Rays for Cancer.—Dr. Despeignes claims to have had a measure of success in treating a case of carcinoma of the stomach with the x -rays. They were passed through the part twice a day for half an hour each time and by the end of a week the patient's condition was markedly ameliorated and the tumor was evidently smaller.

Need of Caution in the Use of the Roentgen Rays.—Dr. W. V. Gage, of McCook, Neb., writes: "I wish to suggest that more be understood regarding the action of the x -rays before the general practitioner adopts them in his daily work. Several cases of alo-

pecia and erythema have followed its use in Omaha and Lincoln, and in one case of my own, when the rays were utilized in trying to determine the presence of a foreign body in the stomach of a child, erythema and finally sloughing took place, leaving a lesion over the region penetrated by the rays, which is at present the size of the hand."

Treatment of Pneumonia.—In the article with this title by Dr. Van Doren, in the issue of August 22d, the second formula was incorrectly printed. Instead of sodii bicarb., potassii tart., $\text{āā } \frac{1}{2}$ iss., it should have read: sodii et potassii tart., $\frac{1}{2}$ iss.

The Unwritten Law.—Commenting upon the proposal to draw up a code of ethics of the British Medical Association, *The Lancet* says that "professional ethics cannot be put into written form. They are essentially 'unwritten.' To write them would be to spoil them. They are like the aroma of some flowers—an aroma which when concentrated becomes offensive."

The Medical Practice Law in Hawaii.—No one is permitted to practise medicine in the Republic of Hawaii without a license. A person wishing a license must pass an examination before the board of medical examiners, and if this is done successfully the board of health is notified, and recommends the minister of the interior to issue a license. All applicants must pay to the minister of the interior a fee of ten dollars. Any violation of this act entails a punishment by fine of not more than \$250. A license may be revoked at any time by the minister of the interior for professional misconduct, gross carelessness, or manifest incapacity.

Smoking and Intellectual Labor.—Dr. Drysdale, writing to the *British Medical Journal*, à propos of certain recently published statistics of smokers among the students of American colleges, recalls some facts discovered by Bertillon in 1855. He found on inquiry made by him concerning the pupils of the Polytechnic School of Paris that 108 of the pupils smoked and 52 did not smoke. He then arranged the 160 pupils into eight divisions, according to the place they held in examination, 20 in each rank, and found that of the 20 who stood highest, 6 were smokers and 14 non-smokers. Of the next 20, 10 were smokers and 10 non-smokers; of the next 20, 11 smoked and 9 did not smoke; thus showing how much higher the non-smoker stood intellectually than the habitual smokers. He also found that the mean rank of the smoker, as compared with that of the non-smoker, deteriorated from their entering to their leaving the school. As a result of Bertillon's inquiry, the minister of public instruction of France issued a circular, addressed to the directors of schools and colleges, forbidding the use of tobacco and cigars to students.

Bichloride Injections in Leprosy.—Dr. H. Radcliffe Crocker reports in *The Lancet* for August 8th two cases of leprosy in which very marked improvement followed deep injections of one-fifth of a grain of corrosive sublimate made once a week for a long period.

Navy Department—Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for two weeks ending August 21, 1896. August 9th, Assistant Surgeon M. K. Johnson detached from the U. S. S. *New York* and ordered to the Coast Survey Steamer *Bache*. August 12th, P. A. Surgeon G. A. Lung ordered to the receiving ship *Vermont*. August 12th, P. A. Surgeon E. R. Stitt detached from the receiving ship *Vermont* and ordered home on waiting orders. August 21st.—Passed Assistant Surgeon A. M. D. McCormick detached from the *Bancroft* and ordered to the Naval Academy. Passed Assistant Surgeon E. M. Shipp detached from the *Monongahela* and ordered to the *Bancroft*.

Patients Poisoned in a Hospital.—A nurse in the City Hospital at San Francisco went out one evening recently, leaving the patients in his ward in charge of one of their own number. This man gave two of the patients a draught from a bottle containing poison instead of the medicine prescribed for them, and they died from the effects of it.

American Microscopical Society.—The nineteenth annual meeting of the American Microscopical Society was held at Pittsburg, on August 18, 19, 20, 1896, under the presidency of A. C. Mercer, of Syracuse. An address of welcome was delivered by Dr. W. J. Holland, chancellor of the Western University. Among the papers read were the following: "Comparative Histology," by Prof. Edith J. Claypole; "Courses in Histology and Methods of Conducting Them," by Prof. S. H. Gage, of Ithaca; "Photomicrography by the Use of an Ordinary Objective Practically Considered, with Specimens of Work," by Thomas J. Bray, of Warren, O.; "On Astronomical Photographs, with Photomicrographic Apparatus," showing pictures of a partial eclipse of the sun taken on an eight-inch focus, by President Mercer; "The Antivivisection Bill," by Pierre A. Fish, of Chicago; "The Acetylene Light as Applied to Photomicroscopy," by William H. Walmsley, of Chicago; "What is the Best Method of Teaching Micro-Science in Medical Schools?" by Dr. Vida A. Latham, of Chicago; "The Structure of the Teeth and Spines of Some Fossil Fishes, *Mazada* and *Ctena Canthus*," by Prof. E. W. Claypole, of Akron, O.; "The Development of the Brain in Soft-Shell Turtles," by Susanna Phelps Gage, of Ithaca, N. Y.; "The Rotifera in Sandusky Bay," by Prof. E. W. Claypole, of Akron, and D. S. Kellicott, of Columbus, O.; "On the Public Water-Supply for Small Towns," by Dr. M. A. Veeder, of Lyons, N. Y.; "The Requisites of a Pure Water Supply," by Dr. William C. Krauss, of Buffalo, N. Y.

The International Congress of Psychologists, which was held this month in Munich, will meet again in Paris in 1900.

Obituary Notes.—DR. J. C. WORTHINGTON, a surgeon in the United States army, died in Louisville on August 11th, of acute articular rheumatism.—DR. ARMAND DESPRÉS, of Paris, died during the first week of August, at Interlaken. He was born in 1834, and was graduated in medicine in 1861. He was a good

surgeon of the olden times, but was such an obstinate Chauvinist that he would never accept the principle of antiseptic surgery, since it was not a French discovery.—DR. C. M. KITTREDGE, of Fishkill-on-the-Hudson, died suddenly at his country home in New Hampshire, on August 19th. He was a graduate of the College of Physicians and Surgeons in this city in 1863.—DR. A. SYDNEY ROBERTS, of Philadelphia, died at Newport, R. I., on August 17th, after a brief illness, at the age of forty-five years. He was at one time a promising orthopaedic surgeon, but he retired from the practice of his profession a number of years ago, and had since, until recently, been living abroad.—DR. ANDREW FLEMING, of Pittsburg, died at Magnolia, Mass., on August 18th, at the age of sixty-eight years. He was a graduate of Jefferson Medical College and a successful practitioner.—DR. WILLIAM F. HERTZOG died at Friedensling, near Reading, Pa., on August 20th, at the age of forty years. He was a graduate of Long Island Medical College and was at one time active in county politics.—DR. JOHN B. HAINES died at South Bethlehem, Pa., on August 15th, at the age of sixty-seven years. He was formerly engaged in the practice of his profession in Philadelphia, where he at one time occupied a seat in city councils, and where he had also been assistant physician to the county prison.

The Cumberland County (N. J.) Medical Society held a meeting at the Hotel Cumberland, Bridgeton, N. J., on July 14, 1896, with the president, Dr. Oliver, in the chair. A paper on "Penetrating Wounds of the Abdomen" was read by Dr. Cornwell. Dr. S. M. Wilson read a paper on "Hydrophobia," in which he questioned the value of Pasteur's method of treatment and emphasized the importance of prophylaxis by means of strict supervision of the dog. Dr. Theophilus Parvin, of Philadelphia, will address the next meeting of the society, which will be held the second Tuesday in October.

Obituary.

WILLIAM HENDERSON WILKES,

WACO, TEX.

DR. WILLIAM HENDERSON WILKES died at his home in Waco, Tex., August 14th, after an illness of six weeks. Dr. Wilkes was born at Raymond, Miss., in 1833, and was graduated at the University of Nashville, in the class of 1855. He enlisted as a private in the Confederate army, and gained rapid promotion for gallant conduct, being retired with the rank of colonel and acting brigadier-general. In 1868 he began practice in Waco, Tex., in which place he had since lived, except for a period of one year, during which he held the chair of obstetrics and diseases of children in Kansas City. In 1882 he was elected mayor of Waco and was reelected in 1885. In 1888 he was appointed professor of the theory and practice of medicine in the Texas Medical College at Galveston, but declined to remove from Waco again. In 1891 he was chosen president of the Texas State Medical Association. In April of the present year he was again elected mayor of Waco, which office he held at the time of his death.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-Fourth Annual Meeting, Held at Carlisle, July 28, 29, 30, and 31, 1896.

(Continued from page 273.)

SECTION ON SURGERY.

First Day—Wednesday, July 29th.

The Surgical Treatment of Prostatic Hypertrophy.—DR. DAVID MACFARLANE, of Dundee, opened the discussion. He referred to the work of Sir Henry Thompson and Mr. Reginald Harrison in connection with the advances in surgery of the bladder, especially its drainage, and to the occasional observation that the symptoms of cases of enlarged prostate had been ameliorated by removal of portions of the prostate gland during the operation of lithotomy. He then spoke of the elaboration of the operation of prostatectomy. The mortality of operations on the prostate undertaken under the usual conditions being still high, attention had been largely directed during the last three years to the results of castration for prostatic hypertrophy, the introduction of which was largely due to Dr. White, of Philadelphia, and whose cases, especially the series published in 1895, showed great success. Owing to lack of time he passed over physiological considerations about the function of the prostate and its relations to the testes, and went on to the clinical experience of the effects of castration and vasectomy. In castration, although the results were valuable, they were not perfect; and then auxiliary methods, such as catheterization and caustics directed to the state of the urine, and sometimes puncture of the bladder, were often employed at the same time. It was difficult to say how much of the benefit was due to these measures. In the record of one series (Ferich's) drainage was used in addition. Of fifty-two operations, forty were successful; eight patients died, and in six no diminution in size was apparent. He had studied the records of thirty-seven cases of resection of the vas, and in twenty-six a good result was noted.

Personally, he had performed double castration for enlarged prostate three times, and resection of the vas for the same cause twice, but had never done single orchidectomy. In the cases of double orchidectomy all the patients had been leading a complete catheter life for some time; in two cases as long as seven years. After operation all were improved, but one patient still used the catheter every twenty-four hours. After two months shrinkage of the prostate was noted, in two cases to one-half the previous size. Also shortening of the urethra was noticed.

He thought that probably the rationale of the shrinkage was a reflex reduction of hyperæmia with subsequent real atrophy. The theories brought forward to explain the exact effect on the gland were discussed, and he leaned to the theory that the changes were due to the medium of the nervous system, but at present the evidence was conflicting. Anyhow, the amelioration of the symptoms, including the return of vesical contractility, was remarkable. He thought that the large soft form of hypertrophied prostate was more amenable than the smaller hard fibroid form.

One objection that had been brought against White's operation was that in certain cases mental disturbances resulted from the operation. With this he did not agree, but thought these symptoms were due to uræmia from the state of the urinary tract and not to the operation itself.

If resection of the vasa deferentia were followed by equally good results to orchidectomy, then the less severe operation would be the better. But at present the statements of results did not agree. As to the results of experiments on animals: In dogs Griffiths found that the testicles were not affected by vasectomy, while others observed atrophy of these organs. White says there is a loss of weight after eight days. The inference was that although in some cases atrophy followed, in most it did not. At present there was no evidence of the result of vasectomy in man, on a normal prostate. He had twice performed the operation; one subject died of uræmia. The other, who had been leading a catheter life for seven years, still required to use the catheter, but some diminution had taken place in the size of the prostate and the symptoms were ameliorated. But the diminution in size was not so marked as in orchidectomy.

He had found no mention of mental disturbances following this operation, save once. He thought it equally difficult to explain the shrinking in this, as in White's operation. White says it is due to certain nerves being included in the ligature. Probably the explanation was to be found in engorgement of the testis from obstruction to its outflow, with subsequent atrophy. In doing the operation both testicles had better be removed at one sitting.

He concluded that in a certain proportion of cases castration was needed, and might be done with good results. In many the hypertrophy was much diminished, and all the symptoms relieved. Vesical contractility may often be restored, but even if contractility did not return relief was obtained. Lastly, vasectomy showed slower and more uncertain results.

MR. REGINALD HARRISON spoke chiefly of division of the vas deferens in cases of hypertrophy, as an alternative to orchidectomy. His method of reasoning appeared to be as follows: Removal or atrophy of the testes in man is followed by atrophy of the prostate. Then in cases in which the vas was destroyed by injury, atrophy of the testicle followed. Therefore, divide the vas deferens rather than remove the testicle, since the operation would be less dangerous.

He divided his own cases into two groups—one group of twelve cases, in which he did single vasectomy; a second group of ten cases, in which the double operation was performed. Of the first group, seven received permanent benefit, and five either showed negative results or were lost sight of. The cases were not of the severest character, but the improvement in symptoms was marked. Of the second group, five received considerable, and he thought, lasting benefit, while the remaining five were either too recent to judge or not benefited. In the double operation he preferred to wait a month or so after the first vasectomy before operating on the opposite side.

The points gained were, diminished frequency of micturition, a lessened use of the catheter, an improved condition of the urine, while the actual catheterization was easier and vesical spasm less marked. He considered that many cases were helped by White's operation or by vasectomy, but some were not amenable to either. He was not opposed to castration; he believed that ill mental results did sometimes follow. He thought that at present we had not sufficient information for selecting cases, and hoped the discussion would help to determine when orchidectomy and when vasectomy would be more suitable.

MR. MANSELL MOULLIN thought that all statistics as to the results of operation were valueless. He did not refer to any particular series, but thought no comparison between the cases was possible, even without the still further disturbing elements of different surgeons and different nationalities. He would himself rely on individual experience alone. He then

went on to point out that the operation of prostatectomy seemed in danger of neglect. This might be due to the high mortality (twenty per cent.) of the earlier cases. But Mayo Robson had done eleven cases with one death, and he himself had had five cases with no death. If septic cystitis and pyonephritis were present at the time of operation, the mortality must be high, but if suprapubic prostatectomy were done while the urine was still healthy the mortality would fall and relief be given. Castration should be reserved for cases which could not withstand suprapubic prostatectomy, or when age was sufficiently advanced to do away with the very real if sentimental objection. He did not believe in unilateral orchidectomy, and gave the case of a gentleman with one testis atrophied from infancy who had a median outgrowth in the neck of the prostate, and in whom no difference in size could be detected in the lateral lobes.

DR. LANDBERG, of Bergen, spoke in favor, both of White's operation and of vasectomy, but thought the first was the more certain. He believed that the nervous theories of the relief were right. As to complete ligation of the whole cord, he recorded a case of gangrene of the testis when such had been done. He dwelt on the difficulty of exact differential diagnosis of all cases, but did not fear that the operations in question would be abused in Norway.

MR. CHIENE said he had an intense respect for the testis, and believed orchidectomy should be done only after all other means of relief had been tried and had failed. He believed the treatment could be summed up into, first, a proper use of the catheter; then, if more were required, suprapubic cystotomy should be performed. If the urine were sweet, a lobe of the prostate might be removed if necessary. If the urine were found septic, the indication would be for drainage, for six weeks, combined with rest; then subsequent removal of a lobe if required. Lastly, he would recommend a perineal tube. But he would advise a man to wear a perineal tube and his testicles, rather than no tube and no testicles.

MR. SOUTHAM, of Manchester, thought that active measures were required in only a small proportion of all cases. He believed in irrigation of the bladder, the use of substances to render the urine antiseptic, and an earlier recourse to the catheter. If suprapubic prostatectomy were employed, a pendulous easily removable middle lobe was often found. If not, a ring or collar of prostatic tissue might be removed, or enucleation (which was a serious operation) of the gland might be attempted. He also advocated drainage through a suprapubic opening for several weeks, or the making of a permanent fistula. Of double castration he thought the results sufficiently encouraging, but all patients did not regain a complete power of voluntary micturition. He had had no actual experience of vasectomy.

MR. MORTON related a case of double castration, in which, although the gland atrophied, about twelve ounces of residual urine remained in the bladder. He believed that the operation of election depended largely on the means and intelligence of the patients.

MR. JORDAN LLOYD thought that there was much nonsense talked and written about the whole subject. Although when younger he had been animated by a burning desire to operate on the prostate of every man who attained the age of fifty-five years, his views had since become modified. He had had a large experience of the ailments of old men, as he was surgeon to the Birmingham Workhouse, and he had been struck by seeing how well these old men with large prostates went on, if let alone. He thought that there was great difficulty in determining the actual condition of the gland, and the treatment must depend on that.

The different varieties of prostatic enlargement were referred to, and he thought that the cases in which prostatectomy succeeded were those of polypoid enlargement, while it did not answer so well when the hypertrophy was general.

In passing he wished to speak most highly of the value of the simple soft Jacques' catheter. It was quite harmless, easily cleansed, and if it could be used no operation was needed.

Again, in examination of the growth the mere rectal examination was a fallacy. Often rectal signs of enlargement were present, but no prostatic symptoms, or no signs of hypertrophy were noted per rectum while symptoms were present. A sound in the bladder and finger in the rectum were much more useful. Cystoscopy might or might not be of use. It gave a limited view only, but should be tried.

Perineal drainage he never used, and he had a patient at present who had worn a suprapubic tube with comfort for eight years.

DR. CAMERON, of Toronto, agreed in the main with Dr. MacEwan's and Mr. Harrison's papers. He preferred the low operation for drainage, since the result as regards the atrophy of the gland was better. He spoke of the possibility of removing the prostate by morcellement per perineum. Also polypoid growths might be dealt with by this method. The researches of Johnson, of Cincinnati, on the production of the menopause by inclusion of nerve fibres in the broad ligaments by ligature were mentioned, and the possibility of good results of interfering with the nerves of testes might be similarly explained.

He had done orchidectomy in nineteen or twenty cases, with one death. The results in all the others except two were good. In these mental symptoms developed, and in one case, in view of the results of Brown-Séquard's investigations, he administered the extract of fresh sheep's testicle with a good result. The other cases got well in a few days. He drew attention to the excellent work of American surgeons.

DR. MACEWAN, in closing the discussion, said that Mr. Harrison's cases of vasectomy were the largest in number he had seen, and, as the results were so good and the operation so harmless, he should in future be inclined to do that first and castration subsequently, if required. He quite agreed that prostatectomy was the most suitable for intravesical growths, but general enlargement must be treated by orchidectomy. In reply to Mr. Chiene's arguments, he did not find that the patients had any sentimental objection to parting with their testicles, but were glad to grasp at any means of relief for the condition. Drainage of the bladder was very useful indeed when patients were too feeble or too reduced to stand any more radical proceeding.

Subphrenic Abscess.—DR. LAUENSTEIN read a paper on "Subphrenic Abscess and its Treatment." He spoke of the first diagnosed case by Dr. Barlow, then of one which came under the care of Dr. Williams in the same year, and finally the more recent work on the subject by Leyden. He defined the condition as a collection of pus beneath the arch of the diaphragm. Its origin might be primary or secondary to affections of neighboring viscera, *e.g.*, stomach, duodenum, kidney. It might be metastatic or due to extension of disease from the thorax or ribs. The general symptoms were not characteristic, and the diagnosis had to be made from local signs—pain, sense of oppression, increased sensitiveness to touch along the side and above the diaphragm. Possibly there might be signs of pleurisy above or of adhesions to intestines below. The diagnosis might be confirmed by exploratory puncture. He discussed the natural method of termination by perforation into the stomach, lung, etc., and

considered that the prognosis depended on whether or not surgical aid were given. He found that only six cases of those left alone recovered, while thirty-nine out of seventy treated surgically lived; so that, as the chance of self-healing was remote, the treatment should be prophylactic in cases in which the condition might be suspected. Here he thought medical treatment was needed. But when it was once developed the surgeon should take charge of the case and the abscess be thoroughly opened and drained, a thick double drainage tube being left in. He gave details of six cases of his own.

Carcinoma of the Mamma.—DR. SNOW read a paper on three hundred cases of operation for malignant disease of the breast. He drew special attention to the insidious marrow lesions, and showed photographs of cases in which the prominence of the sternum was well marked. He gave details of cases, in one of which a woman was operated on for pure scirrhus of six months' growth, and had remained immune up to the present, sixteen and a half years. Another had been free for eleven and a half, another for eight years.

The appearance of carcinoma in the second breast he considered to be always simultaneous with general infection, and although he had removed a second breast in one patient he would never again do so, either simultaneously or subsequently.

The great obstacle to the radical cure was the insidious infection of the marrow, and the practical point was a wide and free dissection of the subcutaneous tissue. Such operations as amputation at the shoulder-joint for the sake of clearing the axilla were necessarily too late, and therefore useless.

Skiagraphs.—DR. DAVIDSON gave a demonstration of the x-rays. He showed numerous photographs. In one case the heart of an adult was well shown. Another was a photograph of a case of coxa vara. In another, of the leg and foot, the tendo Achillis, outlines of muscles attached to the tibia, tarsal bones, and articular cartilages were easily seen. The chief points about the practical working were to have a large and powerful induction coil—one ten inches in diameter was required—and to so arrange the electrodes by manipulating them that the current just takes the lamp, instead of jumping across the space between the electrodes. This was got by placing the ends close and then separating them until the spark no longer passed and the lamp glowed. This he had learned from an interview with Professor Roentgen, who said that thus the maximum photographic effect was got. Also by means of the fluorescent screen the members present were able to see a bullet, lodged somewhere in the thorax, on the left side below the ninth rib in a young adult. It had been in the patient's body about three years.

Oxygen in Surgery.—DR. GEORGE STOKER read this paper, and showed the apparatus required for the use of oxygen in surgery. The progress of the cases, both naked eye and microscopical, was illustrated by slides projected on the screen. The chief points were the very good effect in chronic ulcers of the leg, severe burns, baldness, alopecia areata, and eczema. He showed actual patients. Also the effect on the organisms present in the wounds was detailed. This seemed to be in the nature of getting rid of mixed cultivations and leaving only a pure cultivation of certain organisms which Dr. Stoker found by experience to be harmless, as the patients in whom they were present rapidly got well. The methods for the application in eczema, otitis media, and ulceration of the cornea were also exhibited. The strength of oxygen used was usually twenty-five per cent. The applications, so far as could be judged, were attended with marked success.

Second Day—Thursday, July 30th.

The Surgical Treatment of Appendicitis.—DR. MACDOUGALL opened the discussion on this subject, devoting his time chiefly to the clinical aspects of the affection. It had been asserted that no prognosis could be got from the symptoms. With that he did not agree. The cases could be classed from a clinical point of view as mild simple appendicitis, appendicitis with abscess, appendicitis with perforation, and relapsing cases.

The symptoms to which attention should be directed were pain, tenderness, muscular rigidity, tympany, condition of the temperature, tone of the pulse, presence or absence of vomiting, facial aspect, and, about the third day of the disease, tumor. Examination per rectum should be always practised, and especially gave help in children's cases.

The treatment was absolute rest in bed, fluid diet, leeches, the use of ice bag, but opium only when pain demanded it. Aperients should not be used for fear of risk to any adhesions present. Sometimes enemata were useful, and intestinal antiseptics, such as salol and naphthalin, should be tried. If the case were going on well, a fall of temperature, diminution of tenderness, and lessening of the swelling would follow.

If abscess supervened the symptoms were more severe, the swelling was more acute, and the temperature was higher or rose steadily. The abscess might remain localized or simulate closely general peritonitis. Or there might be suppuration and no local tumor be discernible.

Acute perforative peritonitis was attended by symptoms which cannot be overlooked. Such often came on in persons of previous good health, and with no history of former attacks. These cases were rare, but the liability to perforation gave need for much watchfulness.

The fourth kind showed symptoms similar to simple appendicitis, but there seemed to be a curative process underlying these attacks, as they often became less severe and ceased.

The treatment must in first attacks be prophylactic. The recognition of the cases was often difficult, as the onset was so insidious in character. Then subperitoneal perforation might give rise to doubtful signs. A case was related in which the temperature gradually rose to 103° F. Signs of septic poisoning supervened and a retroperitoneal abscess was found containing two and a half ounces of pus. It was impossible to say when the pus commenced to form. The necessity of early rest to prevent perforation and general peritonitis was absolute.

If the symptoms justified it, after a careful local examination, an incision should be made for exploratory purposes.

In children appendicitis was by far the most common cause of abdominal inflammation. The speaker related a case in which, in a young girl, operation had been undertaken for what was thought to be a perforated gastric ulcer. None was found, but at the post-mortem a large abscess in the iliac region with general peritonitis was discovered. The moral was, when in doubt think of the appendix. Cases of inflammation and even fibroid of the right broad ligament had been mistaken for appendicitis, but usually a bimanual examination would clear that up.

The prognosis depended largely on an early recognition, followed by careful treatment.

As to the treatment, a large number of cases got well without any surgical intervention at all. Of course in the third group of cases there was no question as to the line to be adopted. But in a case of average severity, if the symptoms after forty-eight hours did not show a tendency to increase, then one

should watch and wait. If a quick, thready pulse, vomiting, more pain, and depression came on, with increasing abdominal distention and thoracic breathing, then surgical intervention should not longer be delayed. In children it should be the rule to operate earlier, as their condition changes so rapidly.

In fact, each case must be considered on its own merits, and we must be ready to recognize that we might be sadly deceived. Such a case might seem to be getting well, when sudden symptoms of perforation might come on and in less than forty-eight hours all be over. He instanced a case of a man aged twenty-seven years, who was admitted into a hospital on the third day of the disease. Within twenty-four hours the condition was hopeless and he died in less than four days. Then in cases of strangulation of the appendix it might be impossible to judge from the symptoms how severe the condition was.

As to the technique of operation, usually the oblique incision was best; but the appendix might be found bound down out of reach by adhesions. The appendix might be removed: the wound closed usually without drainage.

In all cases of septic peritonitis the iliac fossa should be carefully explored. Through a median incision the abdomen may be well flushed with saline solution at a temperature of 110° F. if the state of the peritoneum called for it, and the appendix should be removed if the patient could bear it. In some bad cases the patient might be so weak that a general anæsthesia would be fatal. In such local anæsthesia should be used, such as freezing with the spray, and the pus evacuated and abscess drained.

Experiment showed that in many cases the peritoneum did not readily become infected during operation, which was a fortunate fact, since removal of the appendix earlier, during the third or fourth day, was difficult to do without soiling the peritoneum.

Is removal of the appendix absolutely necessary? No. The part might be plugged with gauze and shut off from the general abdominal cavity, and drained with success. To search for and remove every appendix in this condition was poor surgery. The welfare of the patient must be primarily considered and completeness of the operation after.

In deep-seated posterior collections the incision might be well back and the peritoneum easily avoided. If the abscess were well localized, and after incision the appendix was found involved in the abscess wall, it was often best to leave it alone. Of course if intestinal obstruction were present from adhesions, these must be broken down, and protection of the peritoneum by careful disinfection and gauze packing employed.

The various methods of removing the appendix in chronic cases were discussed. He preferred an oblique incision and covering the stump with a peritoneal flap if possible.

He hoped to bring out an opinion as to what were the most valuable signs indicating early operation. The initiation of early operation in these cases was largely due to the work of American surgeons, who drew attention to the statistics of the comparative mortality of cases early operated on and those left alone. From the records of one hundred and fifty-one cases, extending over three years, at the Edinburgh Royal Infirmary, grouped under the headings of appendicitis, typhlitis, and perityphlitis, the mortality was thirty-seven. The mortality at St. Bartholomew's and St. Thomas' was twenty per cent. There were cases without peritonitis and without perforation.

Much depended on the early differential diagnosis, and one should endeavor to make out the stage the lesion had arrived at, as the treatment to be adopted depended on that.

One question was, what would the mortality be if it

became the general practice to operate early? Might not too great precipitation rob the patient of his chance of spontaneous recovery? The operation itself was not a light one: it needed competent assistants and favorable surroundings. The cases were not always straightforward and difficulties often arose. The aid of the surgeon should always be early invoked in these cases by the physician, especially in acute cases.

MR. SOUTHAM said he had operated ten times on the recurrent form. He found the appendix bent and bound down twice, distended twice, in two cases containing hard faecal masses. In four cases suppuration had taken place—three locally, one generally. The appendix was removed eight times.

Medicinal measures he thought powerless to prevent recurrence; the only radical cure was to remove the appendix. And that should be done in the quiescent interval after an attack.

He would not operate after a first attack, but if two well-marked seizures had taken place and any local signs were left, he would proceed to operate. Three of his operations had been after a second attack.

As a rule the appendix would be found either constricted, twisted, thickened, or distended, and there was always a risk of ulceration. In general the result of perforation was fatal.

As to the method of procedure, if possible the stump should be covered with a peritoneal flap.

MR. RUTHERFORD MORISON took the following as guides to operation:

1. After a second attack.
2. Cases accompanied by abscess.
3. All cases of perforation.
4. The sudden onset of urgent symptoms in quiescent cases.

He objected to the incision being made through the linea semilunaris, as the drainage was difficult and paralysis of segments of the rectus muscle resulted from division of its nerves. If in operating an abscess were found quite outside the peritoneum, he would only drain. If the peritoneum were opened the appendix might be found lying on or behind the cæcum and it ought to be removed if possible. He preferred a big incision and packing off the lower end with gauze and sponges. In the female with pus in the pelvis, it should be drained per vaginam.

In peritonitis with pus free in the cavity, simple drainage should be employed. In cases of pocketed pus he spoke of evisceration of the intestines, by means of a large incision from the ensiform cartilage to the umbilicus, and giving the bowels an antiseptic bath.

MR. MORTON, of Bristol, said he would operate in every severe case for fear of general peritonitis. He mentioned Murphy's records of one hundred and forty-one cases, and maintained that without operation certain subjects were bound to die. He had personally operated on two cases. It was impossible from the symptoms to tell the condition of the appendix. As to the risks of operation, Murphy lost only two and Norris had no death in fifty-nine cases. Mr. Treves gave the mortality as eleven per cent. in non-suppurative cases; it was thirty to forty per cent. if suppuration occurred early. He strongly advocated early operation and did not believe any clinical classification possible.

MR. JORDAN LLOYD agreed with the last speaker. He said the clinical phenomena were puzzling, but this was because the appendix was of considerable length, and its blind end was free to swing in any direction. He thought that the varieties of the disease depended on the position of the tip rather than on anything else. The following varieties might be made out

1. The tip in the iliac fossa.

Here the symptoms were classical, and in these cases the iliac swelling might be made out.

2. The tip in the pelvis.

Here there was no iliac swelling, but a finger in the rectum revealed the state.

3. In the lumbar variety there were no iliac or rectal signs, but the swelling appeared in the loin.

4. The tip in these cases swings forward into the abdomen, and these he should call the umbilical variety. There would be a localized swelling or abscess surrounded by a resonant area.

As to treatment, having located the trouble, the operator should make the incision accordingly. The incision will vary with the particular kind of abscess present. He agreed with Mr. Morison as to the great value of a vaginal opening in pelvic cases. In an ordinary iliac case, whether or not he would remove the appendix depended on the condition of the patient. In the lumbar cases, which were the most fatal variety, the incision should be far back, in the abdominal kind over the swelling. If diffuse general peritonitis were present, the middle line was the best place for the incision.

No hard and fast rule could be laid down about early operation, but he had never yet had to regret having operated early.

DR. RENTON said that catarrhal subjects should get well with rest and did. But this should be prolonged from five to seven weeks at least. In relapsing cases the appendix ought to be removed.

He believed in small incisions, to lessen the tendency to hernia. The appendix should not be laboriously hunted for to the detriment of the patient. Curiously enough, in some cases the pain complained of was in the side opposite to the lesion. He thought that in intense cases of suppurative peritonitis, many were lost because the operation was done too late. In cases where the vitality of the patient was low he strongly advised local anæsthesia, washing out of the pus, and getting the patient back to bed as soon as possible.

MR. VERRALL said that in catarrhal cases the physician should give early relief. The relapsing cases became less and less dangerous, but more and more difficult to treat. He believed that the only satisfactory termination of the operation was when the appendix was removed. The total mortality according to two hundred and sixty-four cases collected by Hawkins was fourteen per cent. Murphy in two hundred and seven cases had a mortality of 9.93 per cent., with early interference. Thus an early operation lowered the mortality and saved pain, further attacks, and loss of time, this latter being an important element to poorer patients who could not afford to be frequently lying up for lengthy periods. He preferred a long incision with plenty of room to see the parts, and packing could be used to shut off the peritoneum if necessary. He did not agree about hurrying the actual operation for the sake of getting the patient back to bed soon and trusting to the chance of all being well. He believed in removing every atom of pus by extensive flushing. He emphasized the danger of mistaking a lull in the symptoms for a termination of the disease.

MR. PAUL BRIGHT, of Bristol, said he would like to know exactly when and in how many of the cases Dr. MacDougall proposed to remove the appendix. In his experience the less done in the way of surgical interference—in the early stages, when there was much suppuration—the better, and when the condition was grave neither chloroform, ether, nor any but local anæsthesia should be used.

MR. MITCHELL BANKS questioned whether the Americans had not overdone matters, especially in

the way of statistics. He had never seen such a large number of cases of appendicitis, yet it ought to be quite a common condition to allow such a number of operations being done for it. He used to see cases of typhlitis, but now the cæcum seemed to be suffering from neglect, while the appendix was in high favor. He thought that many of these cases had nothing at all to do with the appendix. If the appendix were so often at fault, what became of it when it had not been customary to remove it? He thought the colon and cæcum might yet be taken into favor again. As to the operation, no rule could be made. The collection was either outside the peritoneum, localized inside the peritoneum, or gave rise to diffuse peritonitis. In his experience all cases of diffuse peritonitis terminate fatally. He rather favored a long horizontal incision. He was much against all unnecessary mystification. The object of the operation was to find pus and let it out. He thought that in some cases the pain complained of was due to the formation of adhesions.

In DR. MACDOUGALL'S reply he pointed out that the mortality after operations done during the acute stage was greater than if the cases had been left to themselves; that is, when operation was done as a routine practice and not on selected cases. He agreed with those speakers who preferred a free incision.

Intestinal Anastomosis.—DR. MITCHELL BANKS read a paper on some experiences with Murphy's button. The points to be cleared up were: Whether it was the quickest and best method of joining the intestine, and whether any serious consequences had followed its use. He gave details of six cases:

CASE I. was a stricture of the ileum close to the cæcum. Owing to the enormous distention of the ileum above the stricture, after the excision of the narrowed portion had been done it was found very difficult to adjust the ends of the bowel. However, by means of stitches at doubtful points it was finally accomplished. The girl died in twenty-six hours from shock, but at the post-mortem it was found that the union was quite efficient.

CASE II.—The patient had a fistula above the iliac crest, through which almost all the bowel contents passed, very little escaping per anum. The condition was one of great distress. The fistula was excised and an end-to-side apposition of the ileum to the cæcum done. The patient did well and lived six to eight months in comfort.

CASE III.—Done for stricture of the colon; the patient died of shock.

CASE IV.—Operation was performed for vesico-intestinal fistula. The affected intestine was excised and the ends were approximated by button.

CASE V.—A very good case, in which an intussusception in a boy was excised.

CASE VI. was that of a woman who had a faecal fistula left after strangulated hernia. This was cured and the intestine united by means of a button, but she refused subsequently to part with the button. In all the other cases the button was passed within four or five weeks. Mr. Banks showed a skiagraph of this patient, in which the locality of the button was seen by means of the x-rays.

In reviewing his cases he decided that the operation was easy, quick, satisfactory, and followed by no ill results.

MR. A. H. TUBBY read a paper on metatarsal neuralgia, a painful condition of the foot first described and explained by Morton (Morton's disease). The pain was often very severe, quite incapacitating the patient. It appeared to be due to squeezing of the digital branches of the nerves to the toes between the heads of the metatarsal bones on either side of these nerves. The diagnostic points were pain of peculiar

character, usually some prominence of the head of a metatarsal bone, as if it had been partly pushed out of place, and the otherwise healthy character of the feet. Relief was obtained in minor cases by a tight instep band squeezing the waist of the foot, compressing the bases of the metatarsal bones, causing the digital ends to diverge and separate, and so take pressure off the nerve. This should be combined with a boot made tight at the instep but broad and roomy for the toes.

In some cases operation was needed, and the head of a metatarsal bone, generally the second, should be excised. The result was good, all pressure on the nerves being removed and symptoms alleviated. Details of cases were given.

Hepatic Abscess.—MR. MORTON reported a case of abscess of the liver discharging through the lung. Many attempts were made with the exploring needle and subsequently by operating to get at the abscess. The difficulty seemed to be due to its having more than one cavity. The point in the discussion was that Dr. Powell was much against exploratory puncture. He said so common was it to find abscess some little time after the exploratory introduction of the needle, that he had come to regard it as cause and effect. He believed in exploratory abdominal incision with examination of the liver. He gave details of his cases. Certainly in one case with a small abscess the size of a walnut on the under surface of the liver, it would probably take a serious amount of needling to discover it.

Third Day—Friday, July 31st.

The Surgery of the Subperitoneal Tissue.—MR. WILLIAM ANDERSON, of London, opened the debate on this subject. He said that although cases of the surgery of this structure were common enough, the literature of the subject was very scanty; that is, the subject taken as a whole. The knowledge on this point was scattered very widely, and he had had to go through a large amount of surgical literature, not only European and American, but even to collect cases from as far away as Japan in order to get the materials for the paper. It was not so much to bring forward new facts, as to collect together what was already known but not systematized, that was the function of his essay.

He was often asked the question, What is the subperitoneal tissue? Generally speaking, it might be defined as the structure between the peritoneum and the abdominal wall. It was a mesoblastic development starting from the neighborhood of the spine, in company with the great blood-vessels, and being carried with them and their subdivisions into various situations. Thus, where the vessels escaped from the abdominal cavity, a process of subperitoneal tissue went with them as their sheath.

The structure was highly elastic connective tissue, with more or less fat, also planes or bands of involuntary muscular fibre. It enclosed veins, arteries, lymphatic vessels and glands, spinal and sympathetic nerves. From its complex character and many connections, it followed that infection of this tissue was one of the commonest developments in surgery.

It had a special relation to the intestine. The gut for about four-fifths of its circumference was enveloped by peritoneum, but about one-fifth—the mesenteric border—is not covered by peritoneum, but was in direct contact with the superitoneal tissue. In the surgery of the intestine that must be borne in mind. The tissue might be directly infected by a leakage from the intestine at this spot. There was a similar arrangement in the broad ligaments, and a salpingitis might thus directly infect the subperitoneal tissue.

When the peritoneum became closely applied to a viscus, it ceased to be any longer demonstrable, *e.g.*, in the four-fifths of the intestine. But every viscus of the abdomen was somewhat in direct contact with it. The tissue might be affected either from the peritoneum or from the viscera. The best way of grouping its affections was as follows:

I.—Inflammation.

Etiological grouping.

1. Idiopathic.
2. Tuberculous.
3. Syphilitic.
4. Anæsthetic.
5. Traumatic.
6. Consecutive.

Regional grouping.

1. Retroperitoneal.
2. Subphrenic.
3. Perinephric.
4. Iliac.
5. Pelvic, parametric.
6. Prevesical.

II.—New Growths.

Primary.—1. Lipoma and fibro-lipoma.

2. Fibroma.
3. Myoma.
4. Sarcoma.
5. Cysts.

Secondary.—1. Sarcoma.

2. Carcinoma.

III.—Hemorrhages.

IV.—Lymph exudations.

V.—Extravasation of secretions or excretions.

VI.—Gaseous infiltration.

VII.—Atrophic and degenerative changes.

He thought that grouping according to causation was more scientific than mere regional classification. The tuberculous and syphilitic forms were rather rare. The traumatic was common, it seeming that almost no injury was too slight to set this up. In other cases the traumatism is set up surgically during operative interference. The consecutive form was the most extensive of all. The inflammation might spread from the parietes, the bones, viscera, etc., and might closely simulate that due to other causes. The following generalizations might be permitted:

Inflammation might arise in the tissue itself, or it might start from neighboring structures, or even in structures outside the abdomen. Thus, from the operation of varicocele, infection might reach the subperitoneal tissue along the process accompanying the veins—in hernia direct extension along the process of subperitoneal areolar tissue forming one of its layers; in castration along the tissue of the cord. Also it might spread from the thorax along structures passing from the thorax to the abdomen.

Then, whatever might be its origin, any or every part of the subperitoneal space might be involved. Thus, a case was recorded in which an abscess opened in the left groin, was followed by one in the right iliac fossa, then by another in the left iliac fossa, and finally an ischio-rectal abscess supervened.

The mode of implication of the tissue might be direct, it might be by perforation into it, or it might be by necrosis of its overlying peritoneum.

Its tendency, once inflammation had set in, was always toward the surface. A localized intraperitoneal abscess usually opened into a viscus. A subperitoneal abscess rarely did so.

Very little was known about its new growths. Primary lipoma in this region was very remarkable. Thirty or forty cases had been recorded, and their tendency was to become enormous in size. They often attained the weight of forty pounds, and the growth was rapid. From this rapid growth the patient might become so

cachectic as to give rise to a suspicion of malignant disease. Owing to the extent of the tumor and the great implication of important vessels, attempts to remove these had been very fatal indeed. Sometimes the lipomata, starting inside the abdomen, might follow along the subperitoneal tissue out of the cavity by one of its openings. Thus, he had published a case of a man with a subperitoneal scrotal lipoma which was of such a size that the scrotum had to be supported on another chair in front of the patient.

The fibromata had much the same peculiarities.

The myomata were usually found in the parametrium.

Sarcomata usually spread so rapidly and such extensive infiltration was set up that nothing could be done.

Fifteen or twenty cases of gaseous infiltration had been recorded; they had usually been in connection with diseased lungs and pleuræ or perforated appendix.

The atrophic form was interesting in connection with the genesis of movable kidney.

DR. MACDOUGALL spoke of the light the paper shed on those extensive cases of inflammation and suppuration of the subperitoneal tissue following appendicitis. He related a case of ovariectomy, in which after the operation the symptoms closely simulated those of severe intra-abdominal hemorrhage. On examination of the pedicle a large subperitoneal abscess was discovered, and evacuation of this was followed by recovery. He referred also to the case of a fistula on the left side of the rectum with a collection of pus high up. This was probably due to disease of the appendix, with extensive burrowing along the subperitoneal tissue.

MR. OGSTON related a case in which a girl of twenty years had such an enormous lipoma that she could not raise herself in bed. It was diagnosed as ovarian, but was larger than any ovarian tumor. On exploratory examination the real state was made out and nothing could be done. In this case there was no cachexia. He also related another case of a lipomatous condition of the omentum simulating an ovarian tumor, and in which the diagnosis was very difficult. In a third case operation was undertaken for a retroperitoneal tumor the size of an ordinary potato. It was found to be a myoma involving the ureter. He removed the tumor and had much difficulty in getting the divided ureteric ends together. They were too short to do an end-to-side union in the usual manner. Finally he successfully brought it together by tucking the upper end inside the lower one and suturing it in position.

DR. LAUENSTEIN related a case of a gentleman, the subject of old right hip-joint disease. Fluctuation could be made out from the rectum to the right iliac region. It was evidently a sinus opening into the subperitoneal space. He spoke also of the hopelessness of cases in which sarcomata growing from the peritoneum had infected the tissue in question.

Intussusception.—DR. RENTON read the notes of three cases of intussusception in which he had operated successfully.

A. B.—, aged ten months. Intussusception of the ileo-cæcal valve. The abdomen was opened, the intussusception reduced, and the child recovered uninterruptedly.

E. L.—, aged eleven months. Intussusception at the splenic flexure of the colon. Operation and recovery.

M. W.—, aged three months. Intussusception twenty-four hours in duration, easily made out per rectum. It was found at the operation that one and a half feet of bowel were intussuscepted. Result good.

These cases were all taken in hand early, and the operation was done as rapidly as possible. They encouraged him to advise operation in all cases. It must be undertaken promptly and before adhesions had been formed.

Clinical Department.

MASKED APPENDICITIS.

By J. ESTILL MILLER, M.D.,

PITTSFIELD, ILL.

I REPORT the following case for the purpose of demonstrating the obscurity of symptoms in some of the severer forms of appendicitis, upon which our textbooks are uniformly silent.

Mr. S. H., aged twenty-six, rather slender and of sickly aspect, came to my office July 9th, complaining of feeling badly; he said he had not been well for two years. He had no particular pain, but general weakness, malaise, and loss of appetite. I found his temperature under the tongue 100° F., pulse 80, bowels fairly regular, no tympanites, tongue dry and covered with a yellow coat. I told him I thought he had malarial fever and advised him to go to bed. Under treatment with laxatives and quinine he did not seem to improve, so July 17th I decided to give him a more thorough examination. I found the stomach, liver, spleen, heart, and lungs about normal; on palpating the abdomen I found in the right lumbar region just above the iliac crest an enlargement about the size and shape of a goose egg, with moderate tenderness over McBurney's point on deep pressure. There was no distention of the bowels. There was another point of tenderness above the sacro-iliac synchondrosis. Morning temperature, 99° F.; evening, 100° to 110° F.; pulse, 80 to 90. I advised him to keep quiet, take nourishing and easily digested food, and apply hot hop poultices.

The patient had a profuse sweat followed by a chill on July 18th, and the evening temperature the following day was 100.5° F.; pulse, 88. The enlargement of the abdomen was slightly more prominent and there was a little more tenderness on deep pressure. I told the family that I thought there was an accumulation of pus and advised an operation. I prepared to operate next morning, but found the patient greatly improved, temperature normal, pulse 68, no tympanites, enlargement not so marked, only slight tenderness, bowels regular; so I postponed operating, as I did not know the cause of the enlargement and thought it might be absorbed. My friend, Dr. Dunn, who was called in consultation, thought it perityphlitis, but later said it might be necrosis of the ilium or vertebral caries. He did not think an operation was indicated. On July 21st I introduced a small aspirating needle, but found no pus. The symptoms remained about the same during the following three days, viz.: morning temperature, normal; evening, 99.5° to 100° F.; pulse, 68 to 76; appetite fair. The patient slept well; at times he had slight distention of the bowels. On the morning of July 25th, as the temperature was 100° F. and the pulse 80, I decided to operate, so I took the patient to Dr. Jno. A. Prince at Springfield. After careful examination he concluded there was an accumulation of pus, although he was in doubt as to its origin. He advised an operation for its removal. With my assistance he operated the same afternoon, making the lateral incision parallel with the iliac crest. He found the peritoneum dark and congested over the enlargement; the adjacent coils of intestines were glued together by inflammatory adhesions, the appendix was indurated and adherent, the tip had sloughed off and was surrounded by a pus sack situated deeply, just above and internal to the psoas muscle, thus producing the pain and tenderness in the back. The abscess contained about four ounces of thick creamy pus. The patient is now making a good recovery. Under the circumstances it was very fortunate that we used

the lateral incision; otherwise the operation would have been rendered far more difficult, if not impossible, on account of the position of the appendix and the extensive inflammatory adhesions.

Some tell us to operate if the pulse runs above 116 or below 60 or when there is high temperature with distention and great tenderness; or, if the attack is mild, to wait and operate after the inflammation has subsided. This is good advice when applied to the proper cases. But what are we to do and what is to be our guide in cases like the above, in which symptoms are so masked and misleading? I firmly believe the patient would have died without the operation. At no time during his illness did the temperature go above 110° F. or pulse above 90.

REPORT OF A CASE OF SECONDARY HEMORRHAGE FOLLOWING TONSILLOTOMY.

By F. A. BOTTOME, M.D.,

NEW YORK.

THE subject of secondary hemorrhage following the operation of tonsillotomy is an interesting one, and increases in interest in proportion to the length of time elapsing between the operation and the appearance of the hemorrhage.

With adults we naturally expect a rather sharp hemorrhage at the time of the operation, especially if the tonsils removed are of the hard type and large in size. If, however, the bleeding stops after a few moments (which it usually does), we feel relieved; and this feeling is intensified if a day has elapsed without a recurrence.

Bosworth gives a very complete *résumé* of this subject of secondary hemorrhage. In most of the cases quoted by him from current literature the hemorrhage occurred a few hours after the operation, and in only two cases after a lapse of twenty-four hours; namely, in Nélaton's case, forty hours; and St. Yves', in which the hemorrhage came on four days after the operation.

I have a history of the case of a boy at my clinic who stated that he had a hemorrhage two days after I had removed the tonsils; but I was not able to satisfy myself that the bleeding was from the tonsils and not from the nose, in which I found a small ulcer.

The following case, however, is, without doubt, one of true secondary hemorrhage, and the length of time intervening between the operation and the appearance of the hemorrhage warrants my reporting the case.

I. D—, aged thirty-one. Parents both living; also several brothers and sisters, and all in good health. He has been a hard-working man all his life, without sickness since childhood, except two attacks of tonsillitis, several years previously. There was no specific history, and there were no bleeders in the family.

He applied for treatment because he wished to join the police force; and, although he passed the physical examination, the examiner informed him that he must have the tonsils removed to avoid the possibility of frequent attacks of tonsillitis.

Examination showed both tonsils hypertrophied and of the hard variety. From the fact that they were of the hard type, and therefore liable to bleed freely if removed by the tonsillotome, I advised the use of the hot snare. But the patient objected, and I therefore used the tonsillotome.

The left tonsil was removed on May 2d, and the only interesting feature connected with its removal was the fact that the blade of the Mathieu tonsillotome broke when it had penetrated only half of the tonsil. This might have been embarrassing but for the fact that a MacKenzie tonsillotome was ready by my side, and

with this I removed the tonsil with the broken blade buried in it.

The bleeding following the removal was unusually slight and stopped entirely in a moment. I decided, however, not to remove the right tonsil at the same sitting, and he returned for the second operation on the following Monday, May 4th, at 9 A.M. He stated that there had been no bleeding nor pain, and he had little discomfort in swallowing.

The right tonsil was removed with no difficulty, and no bleeding to speak of followed the operation.

On May 7th the patient returned with the following history: There had been no bleeding nor discomfort after the removal of the second tonsil, and he had considered himself well until 3 A.M. of Thursday, May 7th, when he awoke to find blood flowing from the mouth and the bed linen saturated with blood. He had tried to stop the hemorrhage with cold water, but, failing, sent for a physician in the neighborhood, who worked on him for an hour before he succeeded in stopping the flow. Even at this hour, 10 A.M., he was still expectorating a little blood.

Examination showed that the right tonsil was covered with a black coagulum, evidently from the application of iron; and from the anterior edge of the tonsil behind the anterior curtain there was slight oozing.

This point I cauterized and then gave him a solution of tanno-gallic acid, which stopped the bleeding effectually. There was no recurrence.

The history of this case shows clearly that it was one of secondary hemorrhage, after an interval of sixty-six hours.

42 WEST ONE HUNDRED AND TWENTY-SIXTH STREET.

A CASE OF CENTRAL LACERATION OF THE PERINEUM.

By SIDNEY L. SMALL, M.D.,

SAGINAW, MICH.

On the evening of July 8, 1891, I was called to attend Mrs. S—, aged thirty-three years, in her first labor. Reaching the patient at eight o'clock, I found she had been suffering moderate pains for several hours, and an examination showed a roomy pelvis, the os dilated, and the head well down. The labor seemed to progress very favorably, and at the end of three-fourths of an hour the pains had increased somewhat in force and frequency, but still were not especially severe. Then came one more severe than any previous one, followed quickly by another, and the second stage was over; but in a most astonishing way. The child had gone straight through the perineum, making a wound as though by a cannon ball and leaving the vulva and anterior portion of the floor intact. I had never seen a case of central laceration. I had probably read the three or four lines which some of the text-books devote to it, but I know that when I saw the condition of things I was sorely surprised. The child was of medium size, and it seemed impossible that it could have passed through so small a space with so little apparent force, for at no time were the pains very severe. After the placenta had been delivered through the same abnormal channel, I made a careful examination of the parts. The laceration extended, with irregular outline, from a point in the central line near the posterior commissure to and including the rectal sphincter, and denuding the lower end of the bowel for half its circumference and about an inch high. There was not much hemorrhage, and I decided to wait for daylight in which to make repairs. Early in the morning, with the assistance of

¹ Read before the Michigan State Medical Society, June 5, 1896.

Dr. Davis and the late Dr. White, I repaired the laceration, using catgut for the deeper sutures, and silk for the rest. The patient made an excellent recovery, and on subsequent examination the parts were found to have healed perfectly throughout. May 17, 1895, I was summoned to the same patient, in her second confinement. The labor progressed much as it had in the former case, and, having in mind my previous experience, I was on the lookout for trouble: a pain somewhat harder than usual coming on, I found the head pressing the pelvic floor and threatening a repetition of the accident. I took a blade of the forceps, passed it under the head, and, using it as a vectis, was master of the situation. I expected a laceration, but was determined it should be in the legitimate way. In this, however, I was agreeably disappointed, for the head kindly accepted the way I had provided, the parts yielded with uncommon readiness, and in a short time the child was delivered, and without any laceration. Convalescence was uneventful, and the woman has remained in good health. In regard to the cause of the liability to this accident, I only know that in the case recited there was a large pelvis, in which the coccyx, because of its shortness and slight curve, offered little resistance to the descending head.

OTITIS MEDIA PURULENTA ACUTA AND CHRONICA.

By J. H. McCASSY, A.M., M.D.,

DAYTON, O.

SUPPURATION in the temporal bone, involving some of the most important structures in the human body, should receive the best attention of the general practitioner as well as that of the aural surgeon. The importance and the danger of this very common affection have undoubtedly been underestimated, and the result is a very large number of deaf-mutes and persons with defective hearing, with perforated drums and with chronic suppuration of the middle ear with its attendant evils. The person who temporizes with a menacing discharge of pus constantly flowing from his ear, without putting forth his best endeavors to have it stopped, voluntarily slumbers on a volcano. It is like a magazine of dynamite, which is inert till percussed. The victim of this latent but dire malady, by slight exposure to cold, may precipitate a fatal mastoiditis, meningitis, or septicæmia.

A superstition of the laity is that running from the ear is beneficial to the individual, giving exit to poison which, if checked, might be followed by other maladies more disastrous in their consequences. Many persons succumb to affections which would otherwise have passed them by had it not been that they were so reduced by constant discharge from the ear. The mortality of acute and chronic otitis media is about two and one-half per cent., and is nearly as fatal a disease as typhoid fever. Of the twelve thousand deaf-mutes in the institutions of the United States and Canada, in about fifty per cent. the condition is attributable to acute inflammation of the middle ear in infancy; scarlet fever of itself being responsible for about thirty per cent. of these cases. The hearing as well as the lives of many individuals are lost annually through neglect and ignorance of the proper management of suppurating ears. Meningitis, mastoiditis, and other fatal complications originate frequently from otorrhœa, and render the patient moribund before the gravity of the situation is appreciated.

There seems to be great diversity of opinion regarding the treatment of chronic suppuration in the middle ear, some contending that any interference

with the ossicles is fraught with evil consequences, while others scarcely await the results of three weeks of conservative local treatment until they dig out the ossicles and tympanum. Sound surgical judgment is necessary at this moment in order to adopt a happy medium between the two extremes. The cause of the trouble should be sought and removed. Free drainage should be established. Caries or necrosis in the tympanum should be dealt with in the same manner as in other parts of the body. Carious ossicles, necrosed bone, and other obstructions to free drainage should be removed. It is reprehensible to continue to pack the auditory canal and middle ear full of boric acid, alum, or other powders, and thereby imprison decomposing material. The person that facilitates the flow of such fetid products into the sewer is deserving of the laurels.

I will now give the history of a few cases in practice to illustrate my method of management of the three most common types of suppurative inflammation of the middle ear, viz.:

(1) Acute otitis media purulenta.

(2) Chronic otitis media purulenta without caries or necrosis.

(3) Chronic otitis media purulenta with caries or necrosis of the ossicles or of the wall of the tympanum.

CASE I.—Acute Otitis Media Purulenta. My son, aged six years, contracted a cold and pharyngitis by riding his bicycle while bareheaded and exposed to inclement weather. He complained of fulness in his left ear, impairment of hearing, and tinnitus. The more serious involvement of his middle ear was indicated by pain in the ear and head, which radiated to the frontal and occipital regions and to the pharynx along the Eustachian tube. After he had suffered with "earache" in his left ear by spells for a few days his temperature rose to 101° to 102° F., and once or twice it reached 103° F. The temperature was taken every few hours. His pulse ranged from 110 to 130. He could hear the watch only on its being pressed against his ear. By the fourth day the pain in his ear, in the side of his head, and along the angle of his jaw on the same side was quite severe. The membrana tympani at first was quite hyperæmic, then it became lustreless and opaque. The long handle of the malleus became obscured and the sharp white point of the short process of the malleus was the only landmark that could be seen. The membrane became sodden and bulging. With the aid of a bright light reflected from the head mirror upon the drum, I made a paracentesis in the posterior and inferior segment by passing a spear-shaped knife through a speculum into the membrana tympani; whitish, creamy, inoffensive pus flowed freely. The ear was syringed out twice or thrice daily with warm soda or sublimate solution (the latter 1 to 5,000). It would be well to say at this point that the sublimate should not be used too often, or in very strong solution, because it is an irritant in a slight degree, and the drug may pass through the ear and down the Eustachian tube into the pharynx and cause mercurial poisoning. A solution of boric acid, carbolic acid, sodium chloride, permanganate of potassium, or any of the antiseptic washes may be used. In fact water, and particularly rainwater, that has been boiled is a good antiseptic and cleansing agent, even without any of the so-called antiseptic medicaments.

After the ear was cleansed each time a few drops of warm solution of boric acid, fifteen grains, and sulphate of zinc, one grain to one ounce, were dropped into the ear and the external auditory meatus was closed with a pledget of absorbent cotton. Politization was practised once daily to keep the Eustachian tube patulous. The little patient said he "could feel the water come into his throat" while his ear was being syringed. The perforation in the drum closed about

the middle of the second week, but a discharge of mucus continued a week longer, when it ceased. As soon as the perforation closed, boric acid or aristol was blown into the external auditory meatus. (Powers should not be blown into the ear when the drum is perforated, especially if the perforation is small or high up, because they are liable to form into crusts, lodge in some inaccessible crevice, and cause irritation.) Four weeks after the ear trouble began the watch could be heard at a distance of fourteen inches, and full hearing power was not restored until the end of four months.

CASE II.—Chronic Otitis Media Purulenta. A young man, aged eighteen, had for ten years suffered from a discharge of pus and muco-pus from his right ear as a result of scarlet fever. Hearing in the right ear for the tuning-fork was four inches; ordinary conversation could be heard at a distance of one foot. There was tinnitus aurium, which was not constant, and an occasional attack of vertigo and earache. The vibrating tuning-fork placed on the vertex was heard quite well in the right ear. The posterior half of the membrana tympani was gone. The ossicles were visible and intact, and granulations were numerous. Inflation yielded the "perforation whistle."

Retention of secretion in the middle ear being the most frequent local cause of the persistence of the suppurative process, the ear was cleansed twice daily with a warm soda or sublimate solution. The granulations were touched with a solution of nitrate of silver, from twenty to forty grains to the ounce, every two or three days, and in less than one month's time all that could be reached were removed. Then two or three drops of absolute alcohol were instilled daily and were retained for two or three minutes, the patient inclining his head to the opposite side, but considerable pain and vertigo followed this operation, and it was abandoned. Then a solution of boric acid, fifteen grains, and sulphate of zinc, one grain to the ounce, was instilled after each cleansing operation, but the discharge did not wholly cease. The external auditory meatus and the skin of the ear was painted with a ten-per-cent. solution of iodide of potassium, which protected the ear from discoloration by nitrate of silver; and five to ten drops of a five to ten per cent. solution of silver nitrate was dropped into the ear daily and the patient turned his head in various directions so that the solution could reach every portion of the middle ear possible. On a few occasions this drug passed through the Eustachian tube into the pharynx, which did no harm. I usually syringed the ear after using the silver, to wash away the white coating, consisting of albuminate of silver formed on the diseased mucosa. Under this treatment suppuration ceased in ten days.

Some years ago I gave peroxide of hydrogen a trial in the treatment of suppuration of the middle ear, but it decomposes on heating, which necessitates its employment at the temperature of the surrounding atmosphere. It is an unstable drug, and is often a positive irritant. I rarely use it, except as a test for the presence of pus.

In other cases a saturated solution of chromic acid or trichloroacetic acid, applied by means of cotton on a cotton carrier, successfully destroyed granulation-tissue masses. The air douche, either Valsalva's or Politzer's, at each syringing was used so as completely to evacuate the pus. This treatment carried out carefully twice daily will cure nearly all, if not all, cases of chronic suppuration of the middle ear in from one to three months, provided the suppurative process is not dependent upon caries or necrosis.

CASE III.—Chronic Otitis Media Purulenta with Caries and Necrosis of the Ossicles. M—, aged twenty years; occupation, nickel plater; the family history was good. He had had a purulent discharge from

his right ear since he was two years old, origin unknown. He had scarlet fever and measles during his sixteenth year, but the discharge from his ear was neither increased nor diminished thereby. The patient had made the rounds of a great many general practitioners and had taken a great deal of patent medicine without being benefited. The patient alleged that most of the physicians put him to work syringing his ear twice or thrice daily and packing it full of a white powder (boric acid) and cotton. On November 5, 1895, the patient came to my office. Examination revealed a discharge of offensive yellowish pus from the right ear, characteristic of caries or necrosis. The superior and posterior two-thirds of the drum membrane was gone. The handle of the malleus was shortened through necrosis. The osseous ring was roughened. There was tinnitus and occasionally earache and vertigo. His hearing power was diminished amid noises. He occasionally experienced difficulty in ascertaining the direction whence sound came. The vibrating tuning-fork placed on the vertex was heard rather better in the right ear. The watch was heard at a distance of six inches.

The treatment described in case No. 2 was employed for two months, as the patient wished to try the effects of systematic local treatment for two months before submitting to surgical operation. Local treatment failed to stop the discharge.

Under a general anæsthetic the rest of the drum membrane, the necrosed incus and malleus were removed with some cholesteatomata, and also a mass of granulations from the attic. The osseous ring was scraped with a ring curette. The operation did not last longer than three minutes, as the hemorrhage was slight. The identity of the malleus and incus was almost destroyed by necrosis.

After the operation, the ear was cleansed daily with a mild antiseptic solution, dried with cotton, and a few drops of borolyptol were instilled. The ear was closed with a pledget of absorbent cotton. All discharge had ceased in three weeks, and the patient was dismissed. His hearing was improved. He could hear the watch at a distance of two feet.

The history of the foregoing cases represents fairly well the three prevailing types of suppuration of the middle ear. The line of treatment employed in each class of cases has been successful in my hands.

The frequent earaches of children, which prevail in winter and spring, when sudden changes occur in the temperature, are often the forerunners of suppuration of the middle ear. Since 1889, owing to the prevalence of the gripe, the list of ear troubles has been enlarged. A large number of cases of suppuration of the middle ear is caused by diving or ducking the head. Even hunting-dogs that dive have otitis media and become deaf. Naso-pharyngeal catarrh, dentition, scarlet fever, measles, diphtheria, whooping-cough, phthisis, etc., are among the most frequent causes of suppuration in the middle ear.

Pott's Disease.—Dr. Lovett, in his article in the *Medical News*, advocates treatment of this disease by recumbency, rather than by ambulatory measures, during the acute stage. He considers that apparatus is intrinsically imperfect, and that it is incumbent upon the surgeon either to insist upon treatment by recumbency or to transfer the responsibility of ambulatory treatment to the parents. This is carried out by having the child lie upon its back upon a frame. The addition of traction to the head and legs he believes to be of benefit, and that it hastens recovery by quieting muscular spasm and improving the position of the spine.

Surgical Suggestions.

Chronic Leucorrhœa.—In a large proportion of cases, more distinctly beneficial results have been derived from the long-continued employment in small doses of arsenical preparations or combinations, such as Donovan's solution, than from any other class of medicine used in the constitutional treatment of chronic leucorrhœal cases generally.—MORE MADDEN.

When Shall We Trephine?—(1) In any fracture of the skull, either simple or compound, when there are symptoms of intracranial mischief. (2) If there is much localized depression, indicating the probability of either immediate or remote consequences. (3) In all cases of punctured fracture. (4) For the removal of foreign bodies. (5) In cases of compression of the brain from blood, pus, or tumor, when the offending cause can be located with a reasonable degree of certainty. (6) In cases of epilepsy, when the traces of the injury originating the disease can be recognized.—BUECHNER, *International Journal of Surgery*, May, 1896.

Objections to Whitehead's Operation.—Dr. Matthews read a paper upon this subject before the Marion County Society (Indiana) recently, and his conclusions were as follows: (1) It cannot be advised except in selected cases; (2) an anæsthetic is necessary in order to do the operation; (3) full and complete paralysis of the sphincters is necessary; (4) the operation is difficult, tedious, and bloody; (5) if union does not take place by first intention, pus accumulates and the result must be an ugly one, if not dangerous, and invites sepsis; (6) it is recommended in doing the operation to remove the whole of the hemorrhoidal plexus which is not necessary to the curing of piles; (7) it can be maintained that secondary hemorrhage is more likely to occur than after the ligature; (8) the function of the parts is greatly impaired.

To Open an Abscess.—Do not use the old-fashioned curved bistoury in opening the simplest abscess. It is unsurgical, because you proceed from within outward—from the unknown to the known. This is a false principle in philosophy, in surgery, and in everything. Cut from the surface inward and you can deal with difficulties in the order in which they occur. Always work with the aid of sight and do not pin your faith on anatomy.—*International Journal of Surgery*, May, 1891.

Purulent Ophthalmia and affections of the cornea, syphilides, etc.:

Aque fl. ʒ iiss.
M. S. Use as a collyrium.

Malarial Hæmaturia, so called, is antimalarial; that is to say, some substance freed or formed by the dissolution of the blood, possibly the hæmoglobin itself, is antimalarial. The facts bear out this statement clinically.—E. R. MARTIN, *Memphis Medical Monthly*, 1896.

Varicocele.—Dr. Rand gives the following as the three principal causes: First, anything that impairs the general vigor of the part, as: 1, Lack of proper support from relaxed scrotum; 2, masturbation; 3, abuse of venery, ungratified desires, etc.; 4, chronic orchitis or repeated attacks of acute orchitis. Second, anything that produces pressure; as: 1, abdominal tumors; 2, enlarged inguinal glands; 3, hernia; 4, trusses or belts worn around the waist; 5, accumulation of fat in the omentum and mesentery. Third, anything that produces prolonged muscular effort; as:

1, prolonged riding on horseback; 2, prolonged rowing; 3, prolonged exercise in running or waltzing; 4, excessive and violent muscular effort; whooping cough, sometimes.

—CESARIS.

Tracheotomy.—The necessity for performing tracheotomy may arise when the surgeon is unprovided with tracheotomy tubes. Disinfect a fairly large hairpin, and bend both ends at a rather acute angle at about the middle of their length. The ends of the branches may then be twisted into small hooks or rings, to which tapes may be attached. The blunt end of the hairpin is inserted in the trachea, and the branches tied by tapes fastened behind the neck. This will serve until proper tubes can be procured. Failing a hairpin, take a stitch on each side of the opening in the trachea with stout silk, and tie the ends behind the neck. Any piece of iron or copper wire, of suitable size, may serve as well or better than the hairpin.—*Alabama Medical and Surgical Age*, April, 1896.

Amputations.—Beyond the saving of blood and as much of the limb as possible, I have never practised any fixed rules as to how to amputate, even in the formation of flaps. We should make the flap always with a view of saving as much as possible of the limb.—DR. WYETH.

Ulcer of Stomach.—When perforation does take place, one of three conditions obtains: (1) If adhesions are scanty, the stomach contents escape into the general peritoneal cavity, and a general peritonitis results. Such is apt to be the case in anterior perforations in which adhesions are the exception, on account of the mobility of the anterior stomach wall or of the adjacent hollow or solid viscera; (2) Adhesions may form and the abdominal contents escape slowly. In these cases there is a localized peritonitis which may advance to an abscess, or the barriers of lymph may yield, especially if on the anterior wall, and a general peritonitis follow, as often happens in appendicitis. If the perforation presents itself posteriorly, the lesser peritoneum may become involved, and a large food of abscess result—subphrenic abscess. Very rarely it has happened that an adherent perforation has produced an abscess in the liver, without other lesion. Abscesses in the spleen are more frequent. (3) Adhesion of the stomach and discharge of its contents into a hollow organ may occur. This is a very infrequent complication, which needs only to be mentioned.—DRS. WEIR and FOOTE, *Medical News*, April 25, 1896.

Fracture of Patella.—Dr. Geo. R. Fowler's method consists in exposing the fragments as an intermediate procedure, i.e., after the immediate effects of the injury have subsided and before ligamentous union has occurred, for the purpose of clearing their surfaces of intervening soft parts, and the application of fixation hooks resembling Malgaigne's, though a single and not a double pair is employed. The incision is made either vertically, transversely, or U-shaped, as indicated, and the hooks are inserted in the line of incision when possible, to avoid separate skin wounds. After carefully removing everything from between the fragments and applying hooks, the parts are stitched with subcuticular silk suture, sterile gauze and cotton are applied, and the limbs are enveloped in plaster-of-paris splints for three weeks, at which time the hooks are removed.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GLEANINGS FROM CARLISLE—THE "JOURNAL" AND LIBELS—PUBLIC HEALTH SERVICE—VACCINATION—NIGHT SHELTERS—ARMY MEDICAL SERVICE—THE VACCINATION REPORT—THE LATE SIR J. MILLAIS—THE THIRD INTERNATIONAL CONGRESS OF DERMATOLOGY, HELD AUGUST 4 TO 8, 1896.

LONDON, August 14, 1896.

A WRANGLE about the *Journal* is the new diversion with the British Medical Association, and at Carlisle was expected to be more piquant than usual in consequence of the recent action for libel against the editor. No one doubts his general astuteness and his ability as a journalist, and it must needs be that discontent will here and there be manifested. But the usual difficulties do not necessitate a perennial crop of grievances. The reference committee seems to have failed. It was said that the libel action would not have been taken had this committee been appealed to, which looks like a confession that an apology would have been tendered. But libels ought not to be uttered, and then apologies would not be required. It is a common impression, too, that no redress is obtainable for any wrong done by the *Journal* unless it is extorted by legal means. There is a number of men in London who are glad that the libel case was tried, because they have in the past been, as they think, victims of similar injustice.

Dr. Kingsbury proposed that no anonymous attack on any individual should appear in the *Journal* without the approval of the president of the branch of which he is a member. The editor said they could "pass such a resolution if they pleased, but then they might as well tear up the *Journal* and close the association." This is an amazing confession, suggesting that the words must have been misunderstood, but they have been duly printed in the *Journal's* own report of the speech. Surely the *Journal* and the association do not exist on anonymous attacks on individuals.

In the section of public medicine there was a discussion on "The Profession and the Public Health Service," by Drs. Nasmyth, McVail, Sykes, Ross, Scurfield, Paget, and others. Most of the speakers were employed in the service and it was natural we should hear of some of their grievances and also their defence about the excess of zeal which has been charged upon them. No doubt they have difficulties to contend with, which occasionally cause friction with other medical men. This has especially been caused by the presumption of a few in visiting other men's patients. It has been decided by the local-government board that they have no right to do so except with the attendant's consent. It is to be hoped, therefore, we shall have no more cases of this excessive zeal.

Dilatoriness in notifying was charged against some practitioners, but the officers of health should remember the difficulties of attendants. It is necessary to avoid mistakes, and the earlier the stage the more uncertain the diagnosis of most infectious diseases. Some speakers admitted that the notification certificate ought never to be questioned, though one or two thought exceptional cases would occur in which a consultation with the attendant should be sought.

Dr. J. A. Dick, of Sydney, gave an account of the failure of an attempt to obtain a voluntary notification of diseases by a medical society of Sydney. A circular was sent, requesting a table to be filled up with certain details which could not be objected to by any one. But the response was a complete disappointment. He hoped this might not damp the enthusiasm

of Dr. Newsholme for a national system of registration of sickness.

Dr. C. R. Drysdale read a paper advocating vaccination and revaccination with animal vaccine, as is required in Germany. He gave a large amount of information and statistics of various countries to demonstrate that vaccination in infancy followed by revaccination at twelve years of age or thereabouts would rid the country of the ravages of small-pox, and that it would hasten this desired end if calf lymph alone were to be employed.

Drs. Gaustang, McVail, and Groves supported Dr. Drysdale's views, and the section passed a resolution that calf lymph should be universally available from a department of State.

Drs. Waldo and Walsh had a joint paper on night shelters, in which the Salvation Army plan was subjected to critical examination with respect to its influence on the public health. It appears that these shelters entail a considerable expense on ratepayers. In one case the direct cost to ratepayers through shiftless paupers being attracted to the locality was stated to be over £800 and to entail the further burden of maintaining some of these paupers for the rest of their lives. A resolution was carried that all night shelters should forthwith be placed under the common lodging-houses act—a view I have previously advocated on other grounds.

Lord Wolseley has been to Netley and distributed the prizes. It was thought he might have an announcement to make about the promised new warrant. But no—he applied unlimited "soft soap" to army surgeons in general and declared of one that he knew no one he would rather have with him in a storming party. Expectation was on tiptoe for the natural corollary, but it came not. Lord Wolseley is a "combatant officer" and would keep down "non-combatants." Even one he would like with him in a storming party is after all a mere civilian, and as such must be denied military rank or position. A natural result of such stupidity is seen in a revelation in parliament the other day, that the government has been able to secure only five candidates more than the actual vacancies to compete for appointments on the medical staff. Competitive, indeed! Must the marking be lowered to fill the appointments?

The vaccination report is said to be signed. It will be issued very shortly and the air is full of contradictory rumors as to its contents. It ought to be of value after seven years' preparation.

I have just heard that Sir John Millais died yesterday afternoon. As president of the Royal Academy of Art, his illness was regarded with much sympathy by the public. His disease was epithelioma of the larynx, which remained in a chronic state for a considerable time, but lately assumed a more active form with attacks of hemorrhage. On Wednesday night the temperature rose to 104° F., which was considered due to septicæmia, and he died the next afternoon.

AUGUST 17, 1896.

This year the dermatologists swept down upon London and during the first week in August occupied the spacious examination hall of the Conjoint Colleges of Physicians and Surgeons on the Thames Embankment. As usual, the work of the meeting was split up into sections, of which the clinical demonstrations and the museum were perhaps the most important. Patients were shown every forenoon from 9 to 10:30, and every afternoon from 2 to 3, while four hours daily were set aside for papers and discussions. If we add the time taken up by oddments, such as lantern demonstrations and general meetings, it will be evident that the scientific pabulum supplied by the congress was of a plentiful and solid nature.

As one would expect, the address of the president, Mr. Jonathan Hutchinson, was broad and philosophical. He pointed out that a generation ago the pure dermatologist was a *rara avis in terris*, whereas he was now to be reckoned by the score. This result he attributed in part to the existence of cheap printing and cheap travelling. Not only were the originals and translations of scientific books within the reach of every one, but it was also easy to visit such historic shrines as the Hôpital Saint Louis or the clinics of Vienna. After all said and done, however, Mr. Hutchinson doubted whether dermatology had more than embarked upon its fuller mission. Many considerations of the utmost value to general pathology could nowhere be more readily worked out than in the skin. From the study of lupus we learned that a tuberculous process may be localized in one patient for a lifetime, progressing only at the borders and never becoming generalized. Still, in the first stage of lupus there was frequently a potency for remote infection, and in such cases the affection was multiple. Diagnosis should be based on essential nature and not upon external appearance. One of the great wants of the specialty was a natural classification of diseases of the skin. The great problem before dermatologists was undoubtedly that of etiology. With the latter proposition every one acquainted with the inwardness of this branch of study would at once cordially agree. An enormous mass of facts had been garnered, and masterly clinical descriptions abounded. But notwithstanding the great advances that had been made, a vast *terra incognita* still awaited the explorer. In England the study of dermatology had never been disassociated from that of general medicine.

The clinical demonstrations were crowded daily by members, many of whom were men of world-wide fame. Naturally a number of the cases, by reason of their rarity, had little interest except to dermatologists. On the other hand, not a few had a practical general value, both as types of disease and as illustrating the effect of various modes of treatment. Thus, Mr. Malcolm Morris showed a case of extensive lupus cured by scraping and the external application of pyrogallie acid. He applied the drug at first in ten-per-cent. ointment, changed every six hours, and rapidly reduced its strength to one per cent. This plan, however, could be carried out only with the patient under observation, as several cases of poisoning from absorption of the drug had been recorded. The indication to stop the acid was smokiness of urine. For out-patients it might be used cautiously in a two-per-cent. strength. Dr. Payne showed a woman who four years since suffered from a severe lupus erythematosus of the face. The disease had entirely disappeared, leaving some inconspicuous scars. Treatment consisted in large doses of quinine (thirty grains daily), and, what most people will regard as of more importance, the external use of a collodion containing five per cent. of salicylic acid. Dr. Radcliff Crocker exhibited a patient in whom a number of granulomatous tumors the size of small marbles had vanished under the internal use of salicylate of soda. In another case a leprosy of the face had very considerably improved under hypodermic injections of corrosive sublimate. During six months forty-five such injections had been given. Dr. Abraham showed a case of Kaposi's disease, the diagnosis of which was confirmed by the distinguished discoverer in person. In another instance Bazin bore out the demonstrator of the disease which bears his name. These incidents afford a striking evidence of the value of such international gatherings. As a matter of course, many curiosities were exhibited. Dr. Walsh showed three cases of linear and arborescent atrophoderma. In two it was associated with rheumatism, and in a third with necrosed

bone. The condition was anomalous. There were several other cases for which the united wisdom of the congress failed to find a name. Dr. Connor brought two twins, eight or nine years of age, who two years before suddenly developed a crop of black freckles round the mouth and also on the mucous lining of the lips and the hard palate. Dr. Eddowes exhibited his own legs, which had well-defined eczematous patches caused by *Primula obconica*. He applied leaves of that plant for six hours, and a rash followed after an interval of fifteen days while sweating freely in a hot room. Dr. Waldo showed a curious lichenoid form of lupus, which is figured in Mr. Hutchinson's "Smaller Clinical Atlas." Indeed, many of the cases were familiar from various published illustrations. Patients were also exhibited by Dr. Colcott Fox, Dr. Pringle, and other well-known dermatologists. These demonstrations were attended by a number of non-specialist physicians. It is interesting to note that little mention was made of thyroid gland, although it is being extensively used in the treatment of many skin diseases.

The next great educational feature of the congress was the museum, which included both general and bacteriological exhibits, under Dr. Sims Woodhead as director, and Dr. Galloway and Mr. Plimmer as secretaries. Of the collection thus brought together one can hardly speak too highly. On all sides one heard the complaint that it was impossible to mark, learn, and inwardly digest more than a limited part of its closely packed contents. There was a capital show of pictures, some of which, for execution and artistic handling, apart from subject, might have graced the line at the academy. Photographs were there in hundreds, notably a magnificent collection from Professor Fournier, of Paris. These sun pictures show what can be done by the photographer in the way of illustrating diseases of the skin. Certainly, in that direction England is far behind several continental countries. Neisser, of Buda-Pest, sent a number of lifelike photographs of morbid conditions. Viewed through a stereoscope, they stood out in bold and sometimes in startling relief, and showed what a valuable aid to teaching might be found in this simple instrument. A fine case of wax models came direct from the collection of the famous Hôpital Saint Louis, while various London medical schools contributed a number of models, specimens, and casts. The microscopes were in hundreds, and their slides were constantly changed. A living *filaria sanguinis hominis nocturna* was shown, and the same parasite was shown in the thoracic muscles and in the stomach of a mosquito. The organisms of *seborrhœa*, a disease which is now attracting universal attention, were shown by Van Hoorn, of The Hague, who has isolated three forms, two of them for the first time. There were many slides of leprosy, *madura foot*, *frambœsia*, as well as of the commoner diseases of the skin. The literature of the subject was illustrated by a large collection of pamphlets, books, and atlases of all shapes, sizes, and periods. But the pervading, prominent feature of the congress was undoubtedly ringworm. An afternoon was devoted to the discussion of that interesting fungus, to say nothing of various lantern demonstrations. Saboraud, the pioneer of the subject, sent a magnificent collection of cultivations of various kinds of *tinea*, both from the human subject and from the lower animals, such as the cat and the horse. There were also two similar Italian and two English sets. Of the last mentioned Dr. Adamson's was notable and extensive. His work has been chiefly among the large-spored varieties, which furnish only about ten per cent. of the total number of cases in man, the rest being of the small-spored kinds. At present the study of the *tinea* fungus is in its early stages, but there can

be no doubt that the rapid accumulation of facts will soon enable observers to arrive at important conclusions. The more we know about this harmful parasite the sooner shall we be able to exterminate it. The matter affects the whole civilized world, and its solution has a special bearing on the medical advisers thereof.

As to papers and discussions, they were manifold, and delivered in a polyglot that was not always confined to the three "official" languages of the congress, namely, English, French, and German. He who would learn what was said will find it written in a volume of proceedings to be issued shortly to members.

So much for the work of the congress, and, sooth to say, its play was nearly as varied and arduous. On Monday the foreign members were informally received at the Café Monico. On Wednesday there was a reception by the lord mayor at the Mansion House, on Thursday a reception at Dr. Stephen Mackenzie's. On Friday a brilliant banquet to the visitors was held at the Hotel Cecil. Among the speakers were Professor Kaposi, Besnier, Lassar, Unna, White, Schwimmer, Campana, and Tarnowski. On Saturday the president invited members to his country house at Haselmere, where they had a further invitation to the house of the late poet laureate, Lord Tennyson.

It was agreed to accept the invitation to hold the next congress at Paris in the exhibition year, 1900.

On the whole, the generally expressed opinion is that the London congress has been the most successful gathering of the kind that has yet taken place, whether regarded from a scientific or from a social point of view.

New Instruments.

A DIRECTOR FOR THE STOMACH TUBE.

By MARK I. KNAPP, M.D.,
NEW YORK.

THIS instrument is practically a metal tube curved at the distal end and cut in two horizontally, the lower part of the curved portion being absent. Thus the instrument consists of three parts: *A*, the palatal; *B*, the pharyngeal, which is united to *A* by the hinge *E*; and *D*, the glossal part. *FF* are projections soldered to *A* to prevent the glossal part

from moving laterally. The bolts *G* at the distal end of the glossal part fit into corresponding notches of the pharyngeal part *B*. The handle is firmly united to the palatal part and has attached to it the trigger *C*, which ends in the shape of a hook. This hook works on the catch *H*, which is attached to the glossal part. A silk cord unites the glossal part with the handle.

The cut represents the instrument closed. This closure is effected in the following manner. First, the pharyngeal part *B* is raised; then, the handle being held with the right hand and the thumb placed on the lower lever of the trigger, the glossal part is taken

between the left thumb and index finger, its catch *H* is brought within the hook of the trigger, and then it is opposed to the palatal part within the projections *FF*. Then the right thumb presses upon the trigger, which brings the glossal part backward, and after the pharyngeal part has been brought down with the left little finger and so held, the right thumb releases its hold from the trigger, which springs the glossal part forward, the bolts *G* entering the notches in *B* and closing the instrument. Simply touching the trigger with the thumb opens the instrument instantly.

The chief advantages of this instrument are two in number: first it may be used as a director and secondly it enables us to dispense entirely with the will of the patient. As a director it absolutely prevents the stomach tube from going anywhere else but into the cesophagus, thus excluding the possibility of its entering the larynx, an accident that every now and then occurs. All that is to be done to insure safety is to bring the director with the tube inserted well back to the posterior pharyngeal wall, and the tube, which must be previously lubricated with warm milk, is then pushed down with the left hand. The time required for arranging the director and getting the stomach tube into the stomach should hardly exceed one minute. This director, dispensing with the will of the patient, at once suggests its utility in children and in nervous patients. Its chief value is in cases of attempted suicide, in which the stronger the patient bites the better the instrument holds after the mouth had once been opened.

In ordinary cases the director could be removed as soon as the stomach tube is about one inch beyond the epiglottis: *i.e.*, as soon as the sensitive parts of the fauces, pharynx, and epiglottis are passed. (The choking and gagging of the patients, especially in nervous cases, are due only to the tube passing those parts and irritating them, which is overcome by the director.) But in cases of suicide, the director must be left in the mouth during the whole washing, when it acts at once as mouth gag, tongue depressor, and director. This director could also be used as speculum for topical applications.

This instrument is made in two sizes, one for adults and one for children.

280 BROOME STREET.

Tight Lacing.—Dr. F. Schuman Leclercq (*Virginia Medical Semi-Monthly*, May 22, 1896, p. 103) says that according to Naunyn there is found constricted liver from lacing in from 20 to 20.5 per cent., but Schroeder states this malformation to be present in 59.5 per cent. When we stop to consider that even moderate lacing impedes considerably the flow of bile without necessarily giving origin to an anatomical groove of constriction, we can claim even a higher percentage of gall-stone disease as being called forth by lacing. However, even the tying of skirts around the abdomen will in due time at least relax the abdominal muscles and interfere with the abdominal pressure, or bring forth other active etiological agents, such as tractions on the gall ducts, on the ligaments, interference with the physiological gall-bladder contractions, causing floating kidney, etc. Any corset and any tight lacing of skirts around the waist must needs in time dislocate at least the liver, or stomach, or colon to a more vertical position, and tractions between these organs will ultimately loosen the protective, complicated, ligamental apparatus of nature. We cannot, therefore, praise enough the honest and noble efforts of the reform corset movement with skirt suspension from the shoulders.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 22, 1896:

	Cases.	Deaths.
Tuberculosis.....	164	93
Typhoid fever.....	48	10
Scarlet fever.....	12	1
Cerebro-spinal meningitis.....	1	3
Measles.....	57	5
Diphtheria.....	73	12
Small-pox.....	0	0

Gastric, Intestinal, and Rectal Hemorrhage.—

Dr. Manley says that while bleeding through the anus is in a general way not to be viewed with the same alarm as that coming from the lungs or stomach, when the hemorrhage is considerable in quantity or persistent it should not be viewed with indifference. The effects upon the stomach are quite invariably emetic; upon the bowels, purgative. Pathological lesions which open the way for gastric hemorrhage are simple ulceration, tuberculosis, or cancer. It is a common clinical observation that large gastric hemorrhage is common among females at puberty and the menopause, and is rarely fatal. *Per contra*, such hemorrhage is extremely rare and also of very serious import in a male, excepting that type of hæmoptysis so general among hard drinkers. In the case of a female, preceding these large hemorrhages there is usually a period of indigestion, anæmia, and loss of strength. Recovery seems to be complete. If the cardinal lesion in these cases is tuberculous ulceration, the bleeding would seem to be a specific. Malignant disease of the stomach is rarely attended by large bleeding. In young men of good habits, sudden or repeated gastric hemorrhage is a most suggestive sign of sarcoma. In the incipient stage of this disease the most pronounced symptom is a severe anæmia with rapid wasting of flesh. It is only when the disease advances upward and reaches the peritoneum that suffering begins. Hence it is that cancer of the viscera becomes recognizable only when it has advanced so far that relief by operation is out of the question. Sarcoma of the stomach is widespread, and is unlike malignant epithelial infiltration (which primarily almost invariably attacks the pylorus); bleeding from the intestine—as in the course of typhoid—is manifest only when evidence of mortal exsanguination, or a state close to it, is apparent; deep shock, collapse, and syncope, all appear in rapid succession. Tuberculous ulceration, though common enough, rarely gives rise to hemorrhage. Malignant disease of the small intestine is rare as a primary affection. Hemorrhage, except at the rectal terminus of the large intestine, is uncommon, if we exclude dysenteric ulceration. As a symptom of surgical lesion it is found in cases of invagination in young children. Any type of ulceration may give rise to bleeding, though this part of the alimentary canal, being devoid of lacteals or peptic glands, is the least vascular.

Traumatic hemorrhage of the colon is extremely rare. When it occurs the blood is ejected in considerable amount undigested and imperfectly coagulated. The colon is so placed that it is well protected against the effect of traumatism. Rectal and anal hemorrhages usually occur from areas close to the verge. By digital examination it is possible to reach into the rectum as far as the insertion of the peritoneal coating or the

beginning of the sigmoid flexure. This marks the utmost limit of direct surgical manipulation. Among predisposing causes of anal and rectal hemorrhage are: the mechanical impediment to circulation peculiar to this situation, the almost vertical direction of the efferent vessels in the standing position, the absence of valves, and the irregular habits of life among human beings—for it does not appear that rectal disease is anything other than very rare in the lower animals. The most common cause is a hemorrhoidal or varicose state of the vessels about the anal verge. Tuberculous, next to simple, ulceration of hemorrhoidal walls is the most prolific cause of exhausting hemorrhage from the anus. Cancer ranks third in frequency. Cancer of the rectum, like the visceral type elsewhere, is not very painful in the beginning, and, with unusual exceptions, large or frequent hemorrhage is not present even when the disease is making most rapid headway and is spreading into contiguous parts. The immediate cause of hemorrhage from the anus is through straining at stool, when a thin-walled, widely distended tumor ruptures. Arterial papillomata of the rectum are not uncommon causes of most exhausting depletions. In these cases the mucous membrane of the rectum investing the external sphincter is studded with minute raspberry papillæ, which are apparently devoid of an epithelial investment and bleed on the least irritation. Operative bleeding from the rectum is a most serious complication in those whose general health is enfeebled, who have become anæmic, or who have been exsanguinated by previous vascular drains. When profuse operative hemorrhage arises on division of large, thick-walled veins, and the momentary gush for an instant floods everything, moderate compression will promptly subdue it. In operating here, as elsewhere, the divided arteries give issue to the greatest loss of blood. If operating within the lumen of the bowel, nothing less than a thorough and complete dilatation of the external sphincter will enable one to expose those arteries which ramify through an area of loose connective tissue and quickly retract far up out of sight. The best way to provide security against dangerous hemorrhage in operative manipulation is to be well prepared for it, and close every bleeding point as we proceed with each stage of the operation. Hemorrhage in all operations on the rectum for malignant disease is often quite unmanageable. In these cases the coagulation is enfeebled. In opening up through an osseo-ligamentous structure like the sacrum in posterior sacral resection, we will note that the vessels are thin-walled, and many of them ramify through tortuous canals or paths in cancellous bone tissue, or through the inter-ligamentous spaces, in places where it is very difficult if not impossible to secure the mouths of spouting vessels. Post-operative or secondary hemorrhages after operations on the rectum are comparatively rare. The rule should be always to secure bleeding arteries before returning the prolapsed bowel within the sphincter. By the adoption of such measures as will insure prompt and safe hæmostasis, there will be but little danger of a large secondary oozing, though, unless all arterial leakage is arrested by ligation, torsion, or the thermo-cautery at the time of operating, dangerous secondary hemorrhage may follow. After the sphincter has contracted and the dressings are applied, the blood, instead of making its way outward, may drain into the empty intestine. The evidence of its presence there is only made manifest by a death-like pallor of the patient, with a thready pulse and impending syncope. The surgeon must judge from constitutional symptoms as to whether hemorrhage is occurring. In many small angiomatic papillæ with sessile bases and deeply embedded vascular rootlets, the thermo-cautery is invaluable; with vessels of larger bore, secure ligation

constitutes our main reliance. The patient should always be watched for several hours after operations within the sphincter. Should hemorrhage ensue, palliative treatment may be adopted for a while, and, this failing, the patient must be put upon the table, the sphincter redilated, and the bleeding point found and secured. Symptomatic hemorrhage from the rectum in persons of full habits must not be confounded with the presence of local lesions. It is nature's way of seeking an outlet for overdistended vessels, and may be avoided by the use of purgative medicine and care in regard to diet. Hemorrhage from tuberculous ulceration is sometimes very profuse. These ulcers usually lie in the posterior wall of the gut. Cancer of the rectum, at least in the early stages, is seldom attended with bleeding. In all these cases pain is a prominent symptom during the act of defecation, but hemorrhage is seldom seen. Gummatous masses usually infiltrate the non-vascular stratum of lymphoid tissue, which near the outlet of the rectum is of unusual thickness. The hyperplasia which they cause may produce stenosis, but rarely ulceration or hemorrhage. Hemorrhage succeeding tuberculous ulceration of the rectum should be treated by local applications and attention to the general health.

The author concludes: Hemorrhage from the rectum may be symptomatic of constitutional or organic disease, as plethora or hepatic congestion. In consequence of a lesion of some part of the digestive tube, anywhere from the flexure to the cardiac end of the stomach, blood may escape, changed or unchanged, through the rectum. The local lesions, in their order of frequency as a source of hemorrhage in the ano-rectal outlet of the intestine, are: (1) hemorrhoids; (2) simple or tuberculous ulceration; (3) malignant disease. Treatment includes constitutional and local measures. Hemorrhage from simple, tuberculous, cancerous, dysenteric, or typhoidal ulceration in any part of the digestive tube above the rectum, is quite beyond relief from direct surgical methods, and hence its treatment must, for the present at least, remain within the domain of medicine. Surgical treatment of hemorrhage of the rectal pouch and anus, when non-malignant, is generally practicable, safe, and permanent in results. In order, however, to be rendered effectual and definite, thorough dilatation of the anus and eversion of the rectum are imperative, that the bleeding points or source of hemorrhage may be brought under the immediate eye for direct and effective treatment. When bleeding succeeds hemorrhoids for the first time, or when its quantity is small, moderate catharsis with simple astringents in the form of suppositories will favor its arrest without recourse to radical or severe methods.—*The Therapeutic Gazette*.

Innervation of the Intestines.—Pal states that not only the stomach, the small intestine, and the upper third of the colon are innervated by the vagus, as hitherto accepted, but also the whole of the colon and rectum. He experimented on curarized dogs, endeavoring to determine whether there were any controlling motor centres for the intestines below the splanchnic centres in the spinal cord. Simple section of the dorsal portion of the spinal cord (from the sixth to the tenth dorsal vertebrae), causes more violent movements when stimulus is applied to the vagus. If the lower dorsal or lumbar vertebrae are removed, the intestines assume a different appearance. (Animals from one-half to one and a half years are best for these experiments.) The vessels become fuller, the intestinal walls thicker, and the intestine itself begins to move with a peculiar motion resembling the pendulum swing of a rabbit's intestines. Stimulus applied then to the vagus produces a much stronger action than before, with a noticeable shortening of the time between

the stimulation and the response. If, however, the lower part of the spinal cord is removed and the nervi splanchnici are severed, the intestines also assume the above conditions. When then the vagus is irritated, violent peristalsis ensues, but this movement is controlled by applying stimulus to the stump of the splanchnicus, which proves the existence of other centres in the spinal cord below the splanchnicus, controlling the peristaltic action of the intestines.—*Centralblatt für Physiologie*.

Late Phlebotomy Best.—Lady (who has a sick husband).—Don't you think, doctor, that you ought to bleed my husband?

Doctor (absent-minded).—No, madam. Not until he gets well.

La Société d'Autopsie Mutuelle, of Paris, was organized in 1876, and has about one hundred members, all scientists of note, several of whom are women. It has for its purpose the placing of the brains of its members at the disposal of surviving members for examination and dissection. Fourteen brains, neatly catalogued, are now contained in a glass case at the end of the meeting-room, and the fifteenth, which was during life the property of M. Abel Havelacque, rector of the Anthropological Society, now rests immersed in alcohol on the table of the dissecting-room, where the man's former associates will meet to weigh, probe, cut, and discuss it.—*Medico-Surgical Bulletin*.

Dental Forceps.—There are about two hundred different styles of forceps made for dentists' use, varying in the sizes and forms of the beaks and in the shapes of the handles. They are made not only to suit every need in practice, but every personal requirement of the practitioner.

It Makes Them Tired.—Foster, the physiologist, says: "The blood of the tired animal is poisoned, and when injected into another animal causes the phenomena of fatigue."

Hasty Delivery of the fœtus is a frequent cause of post-partum hemorrhage.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by Thomas L. Stedman, M.D. In twenty volumes. THE DIAGNOSIS OF TUBERCULOSIS FROM THE MORPHOLOGY OF THE BLOOD—AN ORIGINAL RESEARCH, WITH REPORT OF CASES.¹

By A. M. HOLMES, A.M., M.D.,

DENVER, COL.,

LECTURER ON HÆMATOLOGY IN UNIVERSITY OF COLORADO; HÆMATOLOGIST TO ST. JOSEPH'S HOSPITAL; MEMBER OF DENVER AND ARAPAHOE AND COLORADO STATE MEDICAL SOCIETIES.

It is well known that if the diagnosis of tuberculosis be delayed until it is confirmed by the discovery of tubercle bacilli in the sputum, the most important period has been neglected. When bacilli are found, the patient is already in the active state of the disease, and, in many cases, it is then too late to check it. Therefore the first step in the prevention of tuberculosis should be an early diagnosis. If this can be done before the active state begins, or at its beginning, many may avoid or at least delay the destructive results which otherwise would soon follow.

Authorities quite agree that in tuberculosis there exists a shorter or longer latent or pretuberculous state. This may be inherited or acquired. They also agree that the leucocytes of the blood are tissue-formers. During this so-called latent period the body is undergoing retrograde changes. The body tissues are being constructed of the leucocytes of the blood. Hence it occurred to me recently that, before the disintegration of the gross tissues of the body begins, the blood would show distinct and characteristic signs of a similar nature; and, if so, that a study of these appearances could be made a valuable means of diagnosis in this disease. With this in view I selected a few patients with pronounced tuberculosis, and carefully studied a specimen of blood from each. With each specimen I used absolutely the same technique with reference to taking the films, fixing, staining, and mounting.² Afterward cases with similar blood characteristics were grouped together, and to my surprise I found a remarkable similarity in the histories and clinical symptoms. Hence these studies have convinced me that in tuberculosis the condition of the individual can be interpreted from the appearances of the leucocytes of his blood.

Whether the tuberculous condition be inherited or acquired, we find in such persons a tendency to a more or less extensive tissue disintegration. In tuberculous blood I have found cell disintegration abundant, and especially so in young and middle-aged leucocytes.

Hence the fundamental principle upon which this thesis is constructed is the hypothesis that every individual has a biological prototype in the leucocytes

of his own blood. What is true of the larger organism is true of the smaller. What is true of man is true of the leucocytes of which man is constructed. And conversely, what is true of the cell is true of the individual.

The laws of life are universal. There is no break in their continuity. They vary in degree and not in quality. There are degrees of simplicity and complexity, according to the level upon which the particular organism rests, with reference to its evolutionary ascent. From the primordial, non-differentiated, homogeneous protoplasm of the protozoon, and from the protozoon to homo, vital laws present an unbroken continuity. They do not exist in the cell and cease in the individual. They do not exist in the individual and cease in humanity. But the laws of sociology are the laws of biology, and the laws of biology are the laws of the cell. Hence, upon this hypothesis I shall attempt to show a relation of diagnostic value between certain morphological appearances in the leucocytes of the blood and certain conditions in the patient. For this purpose I shall attempt to show certain

Analogies Between the Leucocyte and the Individual—Analogy in Growth and Decay.—It is the opinion held by the majority of observers, Uskow, Gullard, Ehrlich, and others, that the various forms of leucocytes are mere stages or transitional forms in the life history of the cell. As the child develops by insensible stages to maturity and then declines, so the stages in the life history of the cell pass insensibly one into another.

The characteristics which point to the growth of leucocytes, and from which their ages may be approximately ascertained, are based upon two important phenomena: first, a differentiation or division of the nucleus; second, the appearance of granules in the cell protoplasm.¹

First. As a young leucocyte develops, the nucleus attempts to divide. It first changes from the spheroidal or oval form, by extending a portion of itself in various directions. The forms seen in this stage are characterized as "transitional forms." As the cell continues to develop, many of these nuclei completely divide. The cell then contains two or more nuclei and is called a polynuclear leucocyte.

Second. A very young leucocyte possesses very little cell body, being almost all nucleus. But as it develops the cell body increases in size. The cell body in young cells is non-granular, but is either transparent or basophile. As it develops we often observe a tendency to granulation, the granules at first being transparent or faintly basophile. In health they develop in the cell protoplasm simultaneously with the characteristic transitional changes in the nucleus. As the nucleus reaches the transitional or polynuclear form, the granules become more numerous and change from transparent or basophile to oxyphile. Hence, in health oxyphile granules are never seen except in transitional or polynuclear leucocytes or in mature cells. When they are observed in lymphocytes, or young cells, it indicates a prematurely developed cell

¹ Abstract from paper read before the Colorado State Medical Society, June 16, 1896. A full report of the cases is given in the proceedings of the society.

² It would require too much space to enter into the technique in this paper. I propose to devote a paper especially to this subject at some future time.

¹ The majority of staining-methods are useless in bringing out these characteristics of leucocytes. Hence they are of very little value in the study of tuberculosis.

protoplasm, or a nucleus endowed with low vitality and unable to divide.

Again, when leucocytes reach maturity and begin to decay, the granules of the cell protoplasm become less oxyphile and often faintly basophile. Hence, when phagocytes or mature leucocytes are observed with granules which are only slightly oxyphile, or with a basophile tint, we have a cell that is undergoing disintegration—a cell that is returning to its second childhood. Its granules were first basophile, then became oxyphile, and if the cell lives long enough they again become basophile.

But all cells do not pass through each of these stages. Neither do all children live to maturity and die in old age. As a person may die at any age, so may a leucocyte. As a child with a frail organism rarely reaches maturity, so frail leucocytes often die in their infancy. Leucocytes come from preexisting leucocytes, and here, as well as with the more specialized sperm and germ, the characters of the parent are handed down to the offspring. Hence, if it is correct to claim that an individual has inherited a strong predisposition to disease, it is certainly equally true of his leucocytes. For, as are his leucocytes, so is the individual.

Analogy in Structure.—The histology of the leucocytes, studied microchemically, shows that they consist of four tissues: chromatin and achromatin, tissues of the nucleus; spongioplasm and hyaloplasm, tissues of the cell body. Professor Ehrlich discovered that each of these tissues gives a specific reaction to stains, and that they react differently in health and in disease.

The spongioplasm is a network of delicate protoplasm in the cell body, which surrounds and encloses the globules of hyaloplasm, in the same manner that the skin, mucous membrane, and layers of fascia surround and enclose the larger animal organism and its anatomical parts.

The chromatin is also a network of extremely delicate nuclear protoplasm, which encloses and protects its more delicate tissue, the achromatin, in the same manner that the external membranes of the brain and nerves surround and protect the delicate tissues within them.

Analogy in Functions.—Von Recklinghausen and Cohnheim demonstrated that the leucocytes possess distinct and independent functions. They receive food, grow, migrate, construct, generate, and eliminate. Hence we find in them functions exactly analogous to those in the larger animal.

Analogy in Disease.—If the physiological processes are analogous, why not also the pathological? In gross pathology, when the tissues are changed in their morphological appearances their functions are altered. Therefore, when the cell tissues are changed in their appearances and reactions to stains, their functions are also changed.

Analogy in Tuberculosis.—In tuberculosis of the individual we find a rupture, or evidence of commencing rupture, of the continuity of the enclosing membrane, skin or mucous membrane, according to whether it is surgical or pulmonary tuberculosis. When the membrane is ruptured we find a discharge of broken down or disintegrating tissue.

In tuberculosis of leucocytes an identical process is observed. There is a rupture of or an attempt to rupture the spongioplasm. When this is ruptured a portion of the cell is observed passing out, or it has already passed out, leaving a depression in the cell corresponding to the amount of tissue lost.

When the spongioplasm has not yet broken the cell is distorted, with irregular contour and a portion of the cell protoplasm protruding at various points. Hence, the law that brings about disintegration in the

tuberculous patient brings about the same process at an earlier date in the tuberculous leucocyte. The cells show all degrees of disintegration. The blood serum is loaded with debris from these disintegrating cells. With marked disintegration of lymphocytes, or the young cells, we can safely predict adult cells of weakened vitality. Consequently, the phagocytes or tissue formers will be feeble and inactive. Therefore, with marked disintegration in the leucocytes, it is with absolute certainty that we can predict a similar condition in the larger organism. When this condition exists bacilli find a congenial culture medium in which to lodge and develop, with very little resistance on the part of the phagocytes.

Analogy in Percentage.—Perhaps the most important analogy is between the leucocytes of an individual and the individuals of humanity. Each particular class or type in the normal state represents a definite percentage of the total number. In other words, each leucocyte, whether infant, middle-aged, or adult cell, bears such analogous relation to the totality of cell aggregation which constitutes the individual as each individual bears to the totality of individual aggregation which constitutes the more highly complex organism—humanity.

The statistics of any people will show that there is a fairly uniform percentage of the total population for childhood, for middle age, and for adult life. When these percentages are materially changed, we have reason to suspect something wrong in the vital economy. The same law holds good in the leucocytes of blood. The consensus of opinion among hematologists is quite uniform as to the

Percentages of Leucocytes in Normal Blood.—Neudorfer's classification is approximately as follows:¹ Small lymphocytes, twenty-six per cent.; large lymphocytes, eight per cent.; phagocytes, sixty-five per cent.; eosinophile leucocytes, one per cent. In nearly all pathological conditions there is more or less variation from these percentages. Hence, when we find a marked variation from the above percentages, we may be quite certain that we have a pathological condition somewhere in the organism. The following table prepared from the cases studied will show a variation from the normal percentages of considerable diagnostic significance. And, furthermore, a study of the table will also show comparatively uniform percentages for each type of the disease.

I am indebted to many of the physicians of Denver for numerous cases furnished from their private practice, and I wish here to express my gratitude for their valuable aid in this laborious study. The thirty-five presented represent, as nearly as possible, every stage in the tuberculous condition—those in various stages of the active disease, those who have inherited a strong predisposition, and those in various stages of convalescence.

Summary of Cases.—Incipient pulmonary tuberculosis, 1 to 7.

Incipient laryngeal tuberculosis, 8 and 9.

Convalescent pulmonary tuberculosis, 10 to 14.

Advanced pulmonary tuberculosis, 15 to 21.

Fatal cases of pulmonary tuberculosis, 22 and 23.

Fatal case of tuberculous meningitis, 24.

Last stage of pulmonary tuberculosis, 25.

Tuberculous periostitis, 26.

Tuberculous necrosis of spinal vertebra, 27.

Tuberculous hip-joint, 28.

Tuberculous knee-joint, 29.

Tuberculous adenitis, 30.

Pretuberculous and non-tuberculous, 31 to 35.

¹ To estimate the percentage of each variety of leucocytes, five hundred or more cells should be counted and an average taken.

² The method of distinguishing and classifying the varieties of leucocytes will be given in a later paper.

TABLE I.

No.	Name.	Age.	Percentage of Small Lymphocytes.	Percentage of Large Lymphocytes.	Percentage of Phagocytes or "Neutrophils."	Percentage of Eosinophilic Leucocytes.	Percentage of Myelocytes.	Condition Ascertained from a Study of the Patient.	Condition Ascertained from a Study of the Blood.	Attending Physician.
1	Mr. H.	18	7	17	73	2	$\frac{1}{2}$	Incipient pulmonary tuberculosis; little sputum; few bacilli.	Tuberculous condition marked. Recuperative power good.	Dr. E. R. Axtell.
2	Miss N.	23	13	14	71	2		Incipient pulmonary tuberculosis; very little sputum.	Tuberculous condition marked. Fair recuperative power.	Dr. F. E. Waxham.
3	Mr. H.	26	16	9	74	1		Incipient pulmonary tuberculosis; sputum and bacilli.	Marked tuberculous condition. Strong recuperative power.	Dr. E. R. Axtell.
4	Miss S.	..	11	11	77	1		Incipient pulmonary tuberculosis. Beginning convalescence.	Marked tuberculous condition. Fair recuperative power.	Dr. H. W. McLauthlin.
5	Miss N.	38	13	12	74	1		Strong tuberculous predisposition. Had tuberculosis and recovered. Now threatened with relapse.	Tuberculous condition marked. Strong recuperative power.	
6	Mr. B.	58	9 15	23 12	66 69	2 4	1st count. 2d count two weeks later.	Incipient pulmonary tuberculosis; severe cough; little sputum; no bacilli.	Tuberculous condition well marked. Two weeks later much improved.	
7	Mr. C.	27	12	12	74	2		Incipient pulmonary tuberculosis. Beginning convalescence.	Tuberculous condition marked. Strong recuperative power.	Dr. S. G. Bonney.
8	Mr. J.	25	12	12	74	2		Tuberculous laryngitis; little sputum; bacilli. Improving slightly.	Tuberculous condition marked. Slight recuperative power.	Dr. F. E. Waxham.
9	Mr. M.	56	16	13	70	1		Tuberculous laryngitis and incipient pulmonary tuberculosis; very little sputum; bacilli.	Marked tuberculous condition. Moderate recuperative power.	Dr. Henry Sewell.
10	Mrs. F.	25	26	20	51	3		Incipient pulmonary tuberculosis; no sputum; very little cough. Convalescent.	Tuberculous condition well marked. Strong effort to recuperate.	
11	Mr. U.	32	23	16	59	2		Pulmonary tuberculosis. Convalescing. No cough, no sputum.	Tuberculous condition moderate. Fair recuperative power.	
12	Mr. M.	32	31	6	63	$\frac{1}{3}$		Pulmonary tuberculosis. Convalescent. No cough; no sputum.	Tuberculous condition slightly marked. Strong recuperative power.	Dr. S. G. Bonney.
13	Mr. N.	..	37	8	53	2		Pulmonary tuberculosis. Convalescent.	Tuberculous condition very slight. Strong recuperative power.	Dr. Henry Sewell.
14	Mr. D.	..	32	13	53	2		Pulmonary tuberculosis. Convalescent.	Tuberculous condition marked. Fair recuperative power.	Dr. Chas. Denison.
15	Mr. E.	23	8	8	81	$3\frac{1}{2}$		Advanced pulmonary tuberculosis; abundant sputum; cavity; bacilli.	Marked tuberculous condition. Little recuperative power.	do.
16	Mr. M.	32	7	5	87	1		Advanced pulmonary tuberculosis; large cavity; abundant sputum; bacilli.	Marked tuberculous condition. No recuperative power. Granules with basophile tint.	Dr. W. W. Grant.
17	Mr. H.	55	7	16	74	3		Advanced pulmonary and laryngeal tuberculosis of long standing. Slightly better.	Tuberculous condition marked. Slight recuperative power.	Dr. I. B. Perkins.
18	Mr. X.	38	8	10	81	1		Advanced pulmonary tuberculosis; abundant sputum; bacilli.	Marked tuberculous condition. Slight recuperative power.	Dr. H. C. Crouch.
19	Mr. C.	28	8	10	80	1	1	Advanced pulmonary tuberculosis; abundant sputum; bacilli.	Marked tuberculous condition. Slight recuperative power.	
20	Mr. L.	24	10	8	80	2		Advanced pulmonary tuberculosis; abundant sputum, bacilli.	Marked tuberculous condition. Fair recuperative power.	
21	Mr. H.	30	9	9	82	0		Advanced pulmonary tuberculosis; abundant sputum; bacilli.	Marked tuberculous condition. Slight recuperative power.	Dr. H. H. Bucknum.
22	Mr. T.	22	5	0	89	0		Last stage, pulmonary tuberculosis. Died two days after taking blood films.	Marked tuberculous condition. No recuperative power. Granules with basophile tint.	Dr. S. G. Bonney.
23	Mr. E.	21	6	12	81	$\frac{1}{2}$	$\frac{1}{2}$	Advanced pulmonary tuberculosis. Died one month after taking blood films.	Marked tuberculous condition. No recuperative power.	Dr. C. B. Lyman.
24	Miss C.	16	9	17	73	0	1	Tuberculous meningitis. Died soon after taking blood films.	Marked tuberculous condition. No recuperative power. Absence of eosinophile cells; granules basophile; myelocytes.	Dr. E. P. Hershey. Dr. J. T. Eskridge.
25	Mr. B.	58	9	11	80	$\frac{1}{2}$		Advanced pulmonary tuberculosis; purulent sputum; bacilli. Last stage.	Tuberculous condition well marked. Very little recuperative power. Granules slightly basophile.	
26	Mr. S.	25	35	11	52	2		Tuberculous periostitis. Amputation. Recovery. Blood examination five weeks after amputation.	Slight tuberculous condition. Strong recuperative power.	Dr. L. E. Lemen.
27	Mr. R.	16	7	12	80	$\frac{1}{2}$	$\frac{1}{2}$	Tuberculous abscess of spine with necrosis of vertebra; constant suppuration.	Marked tuberculous condition. Slight recuperative power.	Dr. W. W. Grant.
28	Mr. H.	..	23	15	60	2		Tuberculous hip-joint disease. Improvement slow.	Marked tuberculous condition. Slight recuperative power.	Dr. S. D. Van Meter.
29	Mr. B.	58	21	11	59	9		Tuberculous knee-joint; no suppuration.	Marked tuberculous condition. Bone probably involved.	Dr. John Boice.

TABLE I.—Continued.

No.	Name.	Age.	Percentage of Small Lymphocytes.	Percentage of Large Lymphocytes.	Percentage of Phagocytes or "Neutrophils."	Percentage of Eosinophile Leucocytes.	Percentage of Myelocytes.	Condition Ascertained from a Study of the Patient.	Condition Ascertained from a Study of the Blood.	Attending Physician.
30	Miss M.	22	9	13	77	0	1	Tuberculous adenitis of cervical glands. Severe form.	Tuberculous condition well marked. Feeble recuperative power.	Dr. Chas. Denison.
31	Mr. N.	25	25	13	57	5		Strong tuberculous history. Subject in perfect health.	Tuberculous condition slightly marked. Very strong recuperative power.	Dr. C. B. Lyman.
32	Mrs. N.	28	22	11	65	2½	½	Strong tuberculous history. Marked tuberculous predisposition.	Marked tuberculous condition. Strong recuperative power.	Dr. W. W. Grant.
33	Mr. S.	53	8	21	70	1		Tumor in left side. Diagnosis not made.	Tuberculous condition. Strong recuperative power.	Dr. Chas. Denison.
34	Mr. H.	41	12	13	74	1½		Strong tuberculous predisposition. Not yet broken down.	Tuberculous condition marked. Strong recuperative power.	Dr. Chas. Denison.
35	Miss L.	24	21	6	70	3		Malarious anæmia. No tuberculous history.	Tuberculous condition not present.	Dr. E. R. Axtell.

Of these thirty-five cases six were test cases: 1, 3, 5, 32, 33, and 35. In each of these the blood was examined and diagnosis made without any knowledge of the history or physical condition. These six cases are classified as follows:

Incipient pulmonary tuberculosis, 1, 3, and 5.

Pre-tuberculous, not yet having reached the active stage of the disease, 32 and 33.

Non-tuberculous, 35.

The diagnosis made from the blood was in each of these cases confirmed by the attending physician.

It will be observed that there is no single characteristic in tuberculous blood which, if once learned, will enable us to diagnose the disease. We may have, and generally do have, except in well-advanced cases, three conditions of the cells existing at the same time and found in the same specimen: cells in (*a*) the normal condition, (*b*) beginning disintegration, and (*c*) advanced disintegration. It must be remembered also that there is no distinct dividing line between them. They blend insensibly into each other. Experience alone will enable us to educate the eye to distinguish these varieties.

In the study of tuberculous blood we should not only ascertain the percentage of each type of leucocyte, but also classify each type according to the

Degrees of Disintegration.—Beginning disintegration is characterized by a rupture in the contour of the cell, with globules of hyaloplasm passing out, leaving a depression in the cell corresponding to the amount of tissue lost—cell contour partly destroyed. Complete disintegration is characterized by a complete breaking up of the cell into small masses, and these scattering—cell contour entirely destroyed.

Many leucocytes in tuberculous blood do not show evidence of either of these forms of disintegration, but possess characteristics which a study of the foregoing cases has caused me to interpret as meaning lowered vitality, weakened functions, and

Diminished Recuperative Power.—These characteristics are: (*a*) poorly stained or transparent nuclei; (*b*) granules of phagocytes diminished in number, poorly stained, and scattering; and (*c*) a decrease in number or a marked disintegration of the eosinophile cells.

In many cases these characteristics predominate, while in others they are present in only a small percentage of the leucocytes.

Although the eosinophile cell continues to be enshrouded with much mystery, the recent researches of Kanthack and Hardy, of Cambridge, have undoubtedly given us much light upon the subject. They claim that the eosinophile cells are the advance guards of

the phagocytes. The eosinophile cells first surround the bacilli and throw off some of their granules, or secrete a substance which renders the bacilli inactive, and while they are in this state the phagocytes surround and devour them. Therefore, with this interpretation of their function, in any germ disease where there is a decrease in the number of eosinophile cells, or a marked disintegration going on in them, the recuperative power of the organism is greatly diminished. Hence a study of tuberculous blood should reveal two important points: first, the degree of the tuberculous condition; second, the degree of the recuperative power.

Although the first of these is important, yet we must grant that it is equally important both to the patient and to the physician if we can ascertain the amount of recuperative power possessed by the patient, for upon this depends the probable chances of recovery or ability to combat the disease. If our fundamental hypothesis be correct; if the individual has a true prototype in his leucocytes; if the condition of the one can be ascertained from the appearance of the other; if the leucocytes are tissue formers; if it is true that as are the leucocytes so is the individual, then the real source of the recuperative power should be sought for in the leucocytes.

After a careful study and comparison of the blood appearances in all varieties of tuberculosis I have observed that the nearer the blood characteristics approach the following, the greater is the

Contraindication of Tuberculosis.—Normal or approximately normal percentages of all varieties of leucocytes. Absence of giant lymphocytes. Absence of myelocytes. Very little cell disintegration. Very little debris from disintegrating leucocytes. Well-stained nuclei. Phagocytes with cell-body clearly defined and granules rich in number and well stained. Uniformity in size and appearance of the phagocytes.

While, on the other hand, the following are the

Characteristics of Tuberculous Blood, which vary according to the severity of the case. Marked deviation from the normal percentages of all varieties of leucocytes. Great decrease in percentage of small lymphocytes. Great increase in percentage of phagocytes. Usually, a marked increase in percentage of large lymphocytes. Many giant lymphocytes with irregular contour and protruding globules of hyaloplasm. Eosinophile cells absent or few in number only in severest cases. Myelocytes occasionally present. Marked cell disintegration. Many groups of debris from disintegrating leucocytes. Phagocytes with indistinct cell contour, and granules few in number, poorly stained, and scattering. Marked irregu-

larity in size and appearance of phagocytes, dwarf phagocytes as small as small lymphocytes, giant phagocytes double the usual size with five or more nuclei. Often a clear, narrow, and sharply defined ring separating the nucleus from the cell body in small and large lymphocytes. Phagocytes with granules taking a basophile tint, evidence of approaching dissolution. Grouping together of a large number of phagocytes observed before dissolution. Very little disintegration in red cells.

From a review of blood appearances in the foregoing cases I have made the following

Deductions.—First, that the degree of the tuberculous condition can be estimated by (a) the amount of deviation from the normal percentage of each variety of cells; and by (b) the amount of cell disintegration in each variety.

Second, that the degree of the recuperative power is estimated by (a) the staining power of the nuclei; (b) the percentage of leucocytes with no evidence of disintegration; (c) the abundance of well-stained granules of the phagocytes; and (d) the abundance of eosinophile cells rich in granules.

Differentiation.—With reference to the differentiation of the stages of tuberculosis, much could be given, but time and space will not permit it in this paper. I will give a few points which are most prominent, and probably may be the means of differentiating the pretuberculous, incipient, advanced, and convalescent stages. But in the first place sufficient blood characteristics must be observed to justify the opinion that the tuberculous condition exists. It is then time to look for those points which are characteristic of, and will enable us to designate with reasonable certainty, the class in which the patient is to be placed.

The following tables will show quite plainly the peculiar percentage variation for small lymphocytes and phagocytes in the various stages of the disease.

TABLE II.
PRETUBERCULOUS CASES.

	31.	32.	33.	34.	Normal Percentages.
Percentage of small lymphocytes	25	22	8	12	26
Percentage of phagocytes	57	65	70	65	65

In pretuberculous cases, those which have not yet developed an active lesion, the percentage of small lymphocytes is normal or subnormal; and simultaneously with the decrease in the percentage of small lymphocytes there is an increased percentage of phagocytes.

TABLE III.
CONVALESCENT CASES.

	10.	11.	12.	13.	14.	26.	28.	Normal Percentages.
Percentage of small lymphocytes	26	23	31	37	32	35	23	26
Percentage of phagocytes	51	59	63	53	53	52	60	65

In convalescent tuberculosis the percentage of small lymphocytes is approximately normal or above normal; and simultaneously with the increase there is a decreased percentage of phagocytes.

TABLE IV.
SHOWING RANGE OF PERCENTAGES FOR PRETUBERCULOUS AND CONVALESCENT STAGES.

	Percentage of Small Lymphocytes.	Percentage of Phagocytes.
Normal state.....	26	65
Pretuberculous condition	8 to 25	57 to 74
Convalescent tuberculosis.....	23 to 37	51 to 63

TABLE V.
INCIPIENT CASES.

	1.	2.	3.	4.	5.	6.	7.	8.	9.	Normal Percentages.
Percentage of small lymphocytes	7	13	16	11	13	9	12	12	16	26
Percentage of phagocytes ..	73	71	74	77	74	66	74	74	70	65

TABLE VI.
ADVANCED CASES.

	15.	16.	17.	18.	19.	20.	21.	27.	30.	Normal Percentages.
Percentage of small lymphocytes	8	7	7	8	8	10	9	7	9	26
Percentage of phagocytes ..	81	87	74	81	80	80	82	80	77	65

TABLE VII.
CASES IN LAST STAGE.

	22.	23.	*24.	25.	Normal Percentages.
Percentage of small lymphocytes		5	6	9	26
Percentage of phagocytes ...	89	81	73	80	65

* Tuberculous meningitis an exception. Percentage of phagocytes lower.

TABLE VIII.
SHOWING RANGE OF PERCENTAGES FOR THE ACTIVE STAGES OF THE DISEASE.

	Percentage of Small Lymphocytes.	Percentage of Phagocytes.
Normal state.....	26	65
Incipient tuberculosis	7 to 16	66 to 77
Advanced tuberculosis	7 to 10	74 to 87
Last stage of tuberculosis ...	5 to 9	80 to 89

Deductions.—From the tables we make the following important deductions: first, as the tuberculous condition becomes more marked and the gravity of the case increases, the percentage of small lymphocytes decreases and the percentage of phagocytes increases.

Second, as the tuberculous condition becomes less marked and the convalescence increases, the percentage of small lymphocytes increases and the percentage of phagocytes decreases.

Many other deductions might be made from the tables with reference to the physical condition of the patients. For example, in all cases in which the blood shows the usual tuberculous characteristics together with an increase in the phagocytes to eighty per cent. or over, it is quite safe to diagnose advanced pulmonary tuberculosis with cavity, profuse expectoration, and abundant bacilli; or, if surgical tuberculosis, an abscess with more or less discharge of pus.

I do not wish to be understood as saying that all of the appearances that I have described are necessarily present in each case of tuberculosis. Neither do I wish to say that many of them are not found in other diseases. But I do claim that a peculiar combination of blood appearances is characteristic of this disease, to the extent that they will enable us to make a diagnosis at an earlier date than by any other means that we now possess. It is quite probable that the near future will justify a stronger statement: that from the blood condition we will not only be able to diagnose tuberculosis, but that in many cases it will enable us to distinguish the various stages of the disease, and hence will be a valuable means of following the course of the disease under various methods of treatment.

Summary.—In conclusion I will review this study

with the following summary: That the diagnosis of tuberculosis, from the morphological appearance of the blood, rests upon the hypothesis that each individual has a biological prototype in the leucocytes of his own blood. That leucocytes are independent organisms with functions analogous to those of the larger organism. That they pass through stages of growth and decay. That disintegration of leucocytes may occur at any age. That the leucocytes are tissue formers. That as are the leucocytes so is the individual. That tuberculosis is a disease characterized by tissue disintegration. That in tuberculous blood there is abundant cell disintegration, premature development, premature decay, and more or less deviation from the normal percentages of the various types of cells. That if there is marked disintegration in the leucocytes, it is with absolute certainty that we can predict a similar condition in the larger organism. That tuberculosis possesses a combination of blood appearances, from which a diagnosis may be made earlier than by any other means that we now possess. That these may be recognized by appropriate microchemical stains and under a high power. That they can be recognized even before the disease manifests itself in the individual. That they are sufficiently marked in tuberculous persons, or even in those with a strong tuberculous predisposition, to enable a diagnosis being made from the blood alone, without knowledge of the history or physical condition. That the real source of the recuperative power is to be found in the leucocytes. That thus far no other pathological condition has been found which presents similar blood appearances. That to secure an early diagnosis would enable many to avail themselves of favorable climatic changes, and thereby delay or even prevent the destructive results which would otherwise inevitably follow. And, finally, that if future investigations confirm these deductions, we may look forward to a no distant day when, if we expect to detect tuberculosis in its incipency, we must study the leucocytes.

25, 26 BARTH BLOCK.

THE MICROSCOPICAL PROOF OF A CURATIVE PROCESS IN TUBERCULOSIS; OR THE REACTION TO TUBERCULIN EVIDENCED BY BLOOD CHANGES HITHERTO UNRECOGNIZED.¹

BY CHARLES DENISON, A.M., M.D.,

DENVER, COI.

THERE is urgent need of a gauge to go with treatments claimed to be curative in consumption, by which their relative merits may be determined. There is no lack of "cures," so-called. "The woods are full of them," but the limitation of the curative process common to most of them has never been accurately determined.

Thus far, climate, and the preferable climate is on this eastern Rocky Mountain slope, has proved to be first in the list of remedial means, however its curative power is increased by other agencies.

The latest claimant to curative fame, aseptolin, is by no means an exception to this estimate. The treatment has some merit in it. However, the profession will grant much of the credit to the Frenchman, Déclat, who many years ago put forward the hypodermatic use of phenol, and to Dr. Louis Waldstein, of New York, who in Berlin made prominent the similar use of pilocarpine, as well as to Dr. Cyrus Edson, who by combining them has lately brought the new remedy, aseptolin, into extended use. Yet the

effects have to be acknowledged as considerably limited and not so different in kind as we would wish from those produced by the Shurly and Gibbs method with chloride of gold and sodium and with iodine, or from the more recent effort to saturate the system with creosote.

Tuberculin and antiphthisin (Klebs'), which latter is considered by some (Trudeau and Baldwin) only a modification of the former, have not yet impressed the medical profession with their great worth as a means of treatment, for reasons the profession are probably responsible for, though as a means for the diagnosis of tuberculosis the position of tuberculin is well recognized by veterinarians. It is, therefore, very gratifying to have the hope revived that there may be found a trustworthy means of comparing and judging these curative methods through the microscopic examination of the blood.

It was to apply his method of staining and blood examination in order to determine the cell changes induced by the reaction to tuberculin, that I asked Dr. A. M. Holmes to study with me two of my cases some ten weeks ago. The results are new and I am gratified to present them to you in so clear a form, considering the short time the study has been in progress. Much credit is due Dr. Holmes, for I am unaware that just this method of study and comparison has been carried out by any one else. A short history will enable us to comprehend Case I., which was primarily a pulmonary and afterward a surgical tuberculous affection.

CASE I.—Male, age thirty-eight, first seen July 26, 1895; a banker, married eight years, just arrived from Vermont. His mother, whom the patient much resembled, died of consumption. This patient had la grippe followed by cough two years previously, and last winter another attack, when he had night sweats. His weight, about one hundred and fifty pounds, was not decreased, because of good living and care. He experienced only slight effect of elevation on coming here. Cough was not severe; expectoration was whitish, about one ounce in twenty-four hours, and contained tubercle bacilli, three to five in a field, streptococci, and diplococci. There was some infiltration and dulness at the left apex and very slight impairment of respiratory sound on the right side. Diagnosis, fibro-tuberculosis, first stage. Treatment, to use the inhaler because of the bronchitis and mixed infection and to go into the mountains.

September 6th he had returned from a stay at Idaho Springs and was improved somewhat. The spirometer record had increased from 205 to 225 cubic inches and the manometer record from 95 to 110 millimetres.

September 9th I commenced to give tuberculin (Koch's), with ultimately increasing intervals between the injections. The reactions were light and occurred only after a few of the smaller doses. A maximum dose of about sixty milligrams was reached. The sputum cleared up (the germs disappearing) and finally ceased altogether.

April 14, 1896.—Up to February 7th the lung condition continued most favorable, but the tuberculosis had not been wholly eliminated from his blood, for a small abscess then came underneath the scalp above the forehead, the pus from which was found to contain tubercle bacilli; also, perhaps following a strain of right arm and much pain, which kept him awake nights, an abscess formed and infiltrated the tissues below the right elbow-joint. Each of these conditions improved under drainage, the renewal of tuberculin, and the administration of hypophosphites with hydriodic acid. The scalp abscess has healed entirely, but the trouble in the arm evidently comes from tuberculous necrosis and will necessitate an operation.

April 15th Dr. C. A. Powers operated on the right

¹ Read before the Colorado State Medical Society, June 16, 1896.

elbow and we found, as we expected, necrosis of the ulna. Both front and back sides near the end were affected, the joint perhaps just escaping.

A conservative plan was decided upon—to expose the diseased bone freely and scrape it, after which the wounds were thoroughly packed with iodoform gauze.

June 13th.—The dressings were continued until the wounds had healed by granulations from the bottom. During the time of and preceding the operation on the elbow, for three or four weeks no tuberculin was given, and it was during this period, when the necrosis of the ulna was well under way, that the first blood examination, namely, that of April 11th, was made by Dr. Holmes, indicating, as he stated, a serious inflammatory state of the blood and some bone affection; *i.e.*, “an excess of bone marrow or spleen activity” (see table). The tuberculin was continued and given about every fourth day, from about the first of May to date, in gradually increasing doses (from twenty to seventy milligrams for a maximum dose) till there was finally no reaction to speak of to the larger doses. This was during the time the other four blood examinations were made, the increase of the young or new cells, the small lymphocytes, being in exact harmony with a decided improvement in the patient's condition in every way—in weight, appetite, strength, feelings, mobility of the affected joint, and ability to exercise.

RECORD OF BLOOD EXAMINATIONS.

Cases.	Small Lymphocytes.	Large Lymphocytes.	Neutrophile Leucocytes.	Eosinophile.	Myelocytes.	Remarks.
About the normal.	26	8	65	1	0	
CASE I.						
April 11th, necrosis forming.	6	21	72	$\frac{1}{2}$	1	Average of 500.
May 6th, two and one-half hours after a tuberculin injection.	9	17	72	2	0	do.
May 8th, just before an in- jection, 10:30 A.M.	11	20	66	3	0	do.
May 8th, eight and one-half hours after injection, 7:30 P.M.	18	16	64	2	0	do.
May 19th, seven days after an injection.	32	13	53	$1\frac{3}{4}$	0	Average of 500. Note increase of small lymphocytes.
CASE II.						
April 13th, 5 P.M., before treatment.	7	19	72	1	1	
April 14th, five hours after injection, 4:30 P.M.	16	10	73	$\frac{1}{2}$	1	
April 15th, thirty hours after injection, 5:30 P.M.	16	16	66	1	1	
May 16th, seven hours after injection, 5 A.M.	21	7	72	0	0	Extreme retro- grade meta- morphosis.
June 10th, third day after injection, 10 A.M.	9	13	77	0	1	Evidence of pus formation and retrograde met- amorphosis ex- treme.
CASE III.						
About June 8th, before test with tuberculin.	8	21	70	1	0	Evidencing tu- berculosis.
June 17th, next day after second reaction to tuber- culin.	17	13	70	$\frac{1}{2}$	0	Increase of small lymphocytes and tissue met- amorphosis.

It is hoped the apparent though perhaps only approximate immunity reached in this case will prove to be of a permanent nature, as has been the case with quite a number of patients treated from one to five years ago. Of course these were selected with all the care and precaution possible, as suitable for this method, for none others in my judgment should ever

be given tuberculin except for diagnostic purposes. The progress of the above case and of the one yet to be described, together with the numerical changes in the proportion of the various cells of the blood, are shown in the accompanying table, which Dr. Holmes has kindly prepared for me. To this are added the figures of the normal proportion of the different cells according to Neudorfer, of Vienna, for the purposes of comparison.

For the technique and the interpretation of the staining-proclivities of the cells and of other evidences of repair or degeneration, reference is made to Dr. Holmes' paper.

CASE II.—Miss —, age twenty-two, first examined by me February 17, 1896. Both the patient's sisters are possibly tuberculous, the mother is frail, and the mother's two brothers and one sister died of consumption. Previously to coming to Colorado from Maine, which was about seven years ago, she had neuralgia, some cough and fever, was weak and sick, and had yellow expectoration. In Colorado she greatly improved and the catamenia became regular. She ceased expectorating after one month. When eighteen years old the glands in both axilla swelled. The swelling disappeared in three years, but before that, namely, two years ago, the hard lumps came on the right side of the neck and one year ago on the left side. There must have been as many as twenty on the right side, reaching from the ear to the middle third of the clavicle, and nearly as far down on the left side. Those on the right were the largest, causing marked deformity and two of them were commencing to suppurate. There was little or no expectoration and but slight daily temperature rise. Spirometer record, 130 cubic inches; manometer record, 60 millimetres. Her weight before coming was one-hundred and five pounds, and now was one-hundred and twenty-three pounds. Expansion, 29.5 and 31 inches, a little greater deficiency on the right than on the left side. Remnants of enlarged glands were noted in both axillæ, with some depression in the right infraclavicular space. Physical examination revealed no râles or breaking down of lung tissue, but broncho-vesicular breath-sounds, some dulness, and exaggerated voice at both apices front and rear, with prolonged expiration in the right infraclavicular space. The diagnosis was strumous phthisis, so called, which was proved immediately afterward to be tuberculous by the tuberculin test. The local reaction was shown positively by the high-pitched broncho-vesicular exaggeration in the left interscapular space; this was noted after the six-milligram tuberculin dose, and afterward it was quite general over the lungs. The glands in the neck also began to get harder and there was temperature reaction, which seemed to become excessive, showing extreme susceptibility. The test was stopped to prepare for the enucleation of the glands, and thus get rid of so much tuberculous tissue. This operation was performed by Dr. C. A. Powers, assisted by Drs. O'Connor, Pedersen, and myself, April 29th, and some seventeen to twenty glands were nicely enucleated. It was before and after this operation that the blood examinations shown in the table were made, in connection with very small and infrequent doses of tuberculin.

The value of these examinations made by Dr. Holmes was manifest, showing the coincidence of an abnormal susceptibility and the excessive tissue metamorphosis which was going on. Notwithstanding other signs of improvement in this patient's condition, this discovery contraindicated the pushing of such treatment with so much tuberculous tissue to be gotten rid of, and the moderate use of antiphthisin (Klebs) was substituted, with mild inunctions or the oleate of mercury and the internal administration of syrup of hypophosphites and of hydriodic acid. This is pre-

paratory to the extirpation in the near future of the rest of the glands on the left side.¹ This obstinate diseased condition is of the more interest because of its persistence and the profound infection of the system, as well as because it shows that the glandular enlargements, which we have always thought to be scrofulous, are profoundly tuberculous, though, as in this case, no bacilli are found in the glands removed.

This verifies a statement I have previously made, based upon our inability to find the bacilli tuberculosis in tissues evidently tuberculous, as in adenoid growths in the region of the third tonsil in a patient who afterward died of tuberculosis: namely, that there is a pretuberculous state, of which some evidence besides the bacillus of tubercle must be found. Whether that evidence is to be found, as for a long time I have hoped it would be, in the proper microscopic examination of the blood, or as I believe it does exist in the tuberculin test, there is no doubt in my own mind that the two methods will go hand in hand and verify or check each other, just as surely as do the control tests of the assayers in our sampling-works.

A beautiful illustration of the value of both these tests is now given us in another of my cases (see table, Case 3), whose blood has just lately been examined by Dr. Holmes. I refer to the case he describes, in which I could find no bacilli in the sputum and had diagnosed bronchitis and hydronephrosis, and possibly latent tuberculosis. But Dr. Holmes was sure from the morphological appearance of the blood that the case was one of tuberculosis, he knowing nothing of the kidney complication. I have since tested this patient with tuberculin and obtained a distinct reaction, proving Dr. Holmes' diagnosis to be correct.²

As to tuberculin: I was much impressed by Dr. Hance's statement in his late paper on "The Treatment of Pulmonary Tuberculosis,"³ which verifies my own experience and which I will quote in closing:

"The writer recalls at least four patients who could not continue the use of tuberculin, but subsequently arrested their disease process under proper climatic treatment. After the continuous use of tuberculin, or its modifications, extending over a period of nearly five years, he is of the opinion that patients who are 'relatively cured' by the use of tuberculin and climatic treatment have stronger resisting powers against subsequent infection than those who have secured the same results by climatic treatment alone. In other words, their cure (if one may use such a term) is much more firm and lasting than in other cases."

The Blastomycetes of Sarcoma.—Roncali, of Rome, says that he has found a micro-organism in sarcoma and adenoid carcinoma of the ovary. It is found both within and without the cell. Before it acquires an enveloping membrane the protoplasm is chromatic, but later it has a thick membrane and the protoplasm becomes colorless.

¹ July 26th.—The course of the case to date has been so favorable and the evidence of shrinkage of the glands so conclusive that the patient is urging delay of any operation, with the hope that it may not be necessary.

² The morphological state of the blood indicates an enlarged spleen and tuberculous kidney. At the same time a diagnosis of tuberculous adenoma of the kidney, complicating hydro- or pyelonephrosis and perhaps calculus, seems to be warranted by the gross appearance of this tumor. It reaches from the spine around to within three inches of the navel and from below the sixth rib in front to within two inches of the crest of the ilium, and has oval borders. This conclusion is supported by the history of hemorrhages and discharge of pus in the urine, and the fact that the patient has lived as a miner in high altitudes for thirty years, excepting short sojourns in the East, during one of which, at the World's Fair, in Chicago, his principal attack occurred.

³ MEDICAL RECORD, May 2, 1896.

METHODS OF INSTRUCTION IN FIRST AID.¹

By JAMES E. PILCHER, M.D., Ph.D.,

CAPTAIN IN THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.

AN ancient writer named Agatharachides, in describing the prehistoric race of Troglodytes, dwelt upon their method of displaying fondness for the sick and infirm by affectionately drawing a cord about their necks until they suffered no more—the fact that the sick might object to such drastic measures, or that the patient's life was ended as well as his illness, appeared to cut no figure with the Troglodytes. They were not unlike the gentle Scythians, who were wont to employ a sort of Fabian policy in therapeutics, relieving their dear ones of the ills that beset them by tenderly depriving them of food until Death should arrive and complete their cure, which he invariably did in the most effectual manner.

Human altruism has, however, usually manifested itself in a different way. When, in the early history of our race, the sick received any attention, it was directed in the main toward the prolongation of life as well as toward the alleviation of illness. Efforts looking to the accomplishment of either were not a feature of early days. In case of war, no provisions were made by leaders for the relief of the injured in the field or on the march. The wounded soldier was dependent for help either upon the kind offices of his friends or the tender mercies of his enemies, and in the great majority of cases he was neglected by both, only to expire in lingering agony that was incomparably greater in its suffering than sudden death amid the fury of battle. Death being almost inevitable to the injured man, it is hardly surprising that the wounded warrior of old should have fought desperately until a fatal stroke put an end at once to present pain and future agony.

Wise in their day and generation were those communal soldiers of the Middle Ages, who took their wives with them into the field, in order that they might be assured of suitable nursing in case of a wound. Indeed, the vast companies of camp-followers that were found in the wake of every great army of that and later periods, were composed to no small extent of women, from whose numbers nurses were often secured for a favored invalid. But of organized and systematic assistance to the disabled there was none. The first field hospital in history was not established until the close of the fifteenth century, when Queen Isabella, of Columbian memory, established one at Antiquera. And even this was but a sporadic case, which was hardly duplicated for a couple of centuries, until Larrey and Percy became the fathers of the military sanitary system which has attained so great a development at the present day. During that period, however, surgeons progressed from the position of personal attendants upon great commanders to a recognized official station, with duties toward soldiers as well as officers. Finally, the trained sanitary soldier was conceived and created. The instruction of a certain number of the soldiers of the line in the treatment of emergencies and the preparation of cases for the trained sanitary soldiers became a fixed fact, and now the magnificent conception of instructing the entire enlisted force in the elements of first aid has been evolved and put in operation.

The methods of rendering relief were even cruder than the plan of organization. The few surgeons who accompanied armies in the retinue of royalty and nobility were themselves in the majority of instances mere ignorant pretenders, able to give only the most

¹ Read before the Association of Military Surgeons of the United States at Philadelphia, May 14, 1896.

unintelligent and blundering kind of assistance. When the presence of surgeons in military commands became more general and of better quality, their help was still inefficient and incompetent, and this condition persisted almost up to the present day. The brancardiers of Percy were litter bearers, not emergency men. The care of the wounded even in hospitals was of a most defective character as recently as in our war of the rebellion, and the battlefield assistance was confined to the medical officers aided by the "horse sense" of the wounded man's comrades. The thousands of deaths that occurred from a lack of an acquaintance with the methods of applying temporary aid, and the thousands more that ensued from sheer neglect owing to the lack of sufficient attendants and of proper organization among the few who were present, can never be sufficiently regretted. In more recent wars progress has been made; but, as a matter of fact, no military medical organization has yet been able unassisted to grapple with the huge masses of sick and wounded incidental to a great campaign. Solferino, with its five leagues of battleground thickly strewn with wounded in every stage of agony and lingering despair, incited the different nations to establish Red Cross societies. Yet in the Franco-German war, when these societies put forth all their strength and struggled with unexampled energy, the wounded remained at Sulz on the battlefield absolutely deserted and additionally tortured by cold and hunger for three days; and at Gravelotte, where the ambulances could not arrive in time, the greatest suffering resulted among the wounded. At the beginning of the Russo-Turkish war, the Russian official medical service compelled the admiration of connoisseurs, who asserted that nothing was left for others to do; yet, during the progress of the campaign, the efforts of the official medical service, the exertions of the Red Cross societies, and the benevolence of private individuals were all strained and taxed to the utmost in the endeavor to succor the prodigious masses of sick and wounded troops.¹

The work of the sanitary corps of the Japanese army in the recent Chino-Japanese war was effective in the extreme. An observer remarked: "While the storm of lead was still hurtling thickly through the air, a company of Red Cross men, always well to the front, appeared on the field, stolidly marching out from the ravines, two and two, with stretchers and first-aid appliances for their comrades, right under the withering fire from the gunboats, with never a moment's hesitation. Unarmed but for a paltry dirk at the side, helpless in any case against attack, with foes heedless or ignorant of the sacred significance of the Red Cross badge, they did not flinch for a moment on their errand of mercy. It would have been easy to wait until the fire should cease, but they nobly went on and did their duty as if on the parade ground at home. One by one, the dead and wounded were sought out all over that wide field of blood and borne away, until within twenty minutes the place was cleared of every man, living or dead." It was a most splendid example on a small scale of what first-aid organization and instruction can accomplish.

When a nation so new in Western civilization as the Japanese can produce results which command the admiration of the world to such an extent as in this instance, who can deny the *raison d'être* of instruction in first aid? The duty of rendering first aid to the injured after an engagement is characterized by Longmore as a "vast and serious concern, not merely important in respect to preventing aggravation of existing suffering, but upon it depends the question of life itself in numerous instances, and in many others the whole future condition of the wounded, whether it

shall be one of continuous pain and of comparative uselessness, or the reverse of these conditions." With so much dependent upon a proper knowledge of the subject, the question of the best methods of popularizing such knowledge is of the gravest importance.

By common consent, the meaning of the expression "first aid" has been restricted to the temporary assistance to be rendered by persons without medical training in the interval between the accident or emergency and the arrival of a medical man. Emergency surgery and emergency medicine are subjects excellently taught in many medical colleges to embryo practitioners of medicine, but first aid is far from being taught in the same proportion to the general public. During the last score of years, however, much progress in this direction has been made, largely through the influence of the St. John Ambulance Association of England. Thousands of civilian practitioners throughout the United Kingdom, Australia, Canada, China, Germany, Gibraltar, the East and West Indies, Malta, New Zealand, Russia, South Africa, and our own country, in addition to military surgeons, have undertaken the instruction of classes in first aid. The extensive amount of experience thus accumulated, supplementary to the military observations of many countries, is now available for examination and sifting in order to evolve the best method of teaching.

It was but natural that the oral method should have been the first to be adopted in teaching first aid. It was simply a recurrence to first principles. It was the way Adam taught Cain the gentle avocation of butchery and Abel the homely craft of horticulture. It was a most effectual method where the instructor was possessed of the art of putting things and the audience endowed with the faculty of rapid perception. But in these days we have not the phenomenal memories of other days, when all teaching was oral. Aids to the recollection are necessary not only on account of degeneracy of memory, but because the enormously increased extent of the field of knowledge has rendered it impossible for one mind to retain it all in detail. Niccolo Bertruccio, the greatest anatomical teacher of his epoch, taught the whole subject of anatomy in the eleventh century at Bologna in four lectures. But who would be so preposterous as to attempt to teach the subject as it is now known in a dozen times that number?

No description can take the place of a picture. The earliest form of writing was picture writing. The picture writing of the American Indian to-day is graphic and expressive in the extreme. Never was man such a master of word painting that he could equal the sun for accuracy and suggestiveness. The pencil, the brush, and the camera are of the greatest value in making clear instruction in first aid. The thirteen cartoons of Henri de Mondeville, upon which the entire instruction in anatomy at the Paris School of Medicine in the thirteenth century was based, are famous in medical history. The anatomical drawings of Bartolommeo Eustachio were so vivid and accurate, that when they were discovered a century and a half after his death and published for the first time, they rescued his name from oblivion and emblazoned it high on the tablets of immortality. The interest displayed by a class in anything like a picture is evidence enough of the value of this element of instruction in first aid.

Early in the history of such instruction, the value of practical demonstrations was recognized, but these varied greatly according to the taste and wit of the lecturer. It is difficult for many a man to place himself in the position of treating an actually injured man in the absence of an actual patient; it is sometimes equally difficult to find a person who is willing to assume the rôle of an injured man, while it is

¹ Roberts' "Ambulance Work."

rarer still that one can be found with the ability to assume the rôle in a realistic manner. There can be no question, however, as to the value of the practical demonstration; for, if conscientiously carried out, it will not only clarify the whole proceeding in the mind of the learner, but many points will be brought out unconsciously by the demonstrator. The training of the surgeon makes many things second nature to him which are absolutely beyond the ken of the non-medical man. These little essential features of treatment come to light in the practical demonstration. The demonstration also serves to correct in the mind of the learner misapprehensions into which he may have been led by ambiguities or technicalities in the words of a speaker. However careful a medical man may be in his effort to bring his language down to the comprehension of the uninitiated, some technicality, some scientific expression, precision itself to the physician but conveying no idea whatever to the layman, is more than liable to creep in and obscure the sense of his explanation. This the demonstration will entirely correct.

And then, as with the invention of printing the old medical teachers put their prelections into type in order that their students might have copies constantly at hand as aids to memory, so the earlier first-aid instructors came to put their lectures into book form for the benefit of their classes. The "Erste Hülfe" and the "Samariterbriefe" of von Esmarch, the "Ambulance Work" of Roberts, the "Ambulance Lectures" of Martin, the "Emergency Notes" of Butler, and many others were of this class, and are very attractive reading because of the colloquial style in which they were expressed. The little first-aid handbook of the late Surgeon-Major Shepherd, of the British army, was brought out by the St. John Ambulance Association, and a host of imitators sprang up all over the world. There was a demand, however, for more thorough systematically arranged text-books upon the subject, which has been met by the publication of a number of more extensive books, which are now the recognized authorities upon the subject in this country. The crop of the smaller and more defective little manuals continues to be active, every year producing one or two. There is no especial use for them; they are rarely in any way an improvement upon the original compend of Shepherd. Their only advantage seems to be that they excite an interest in first aid among the author's friends and adherents and certainly in the author himself, thus proving to be valuable agents in the propagandism of the subject. Whether this is counterbalanced by the fact that many of their readers are likely to look upon the compend as the sum total of the subject and to look no further, is a question. If, as is the case with the first-aid instructor in a metropolitan branch of the Red Cross Society, the teacher calls attention to the incomplete character of his own book and recommends the study of a more extensive one in addition, the only objection is wiped out. The proper use of the abbreviated manual is as a pocket book for constant carriage in the pocket as a remembrancer of the facts which have been learned by the study of a larger one. The use of two books in this way is certainly an excellent practice, as will be seen in detail farther on.

The use of the text-book is best completed by the addition of recitations. A cultivated and experienced student may, perhaps, be able to absorb the contents of a book by simple perusal, but the ordinary reader cannot. Few persons have gotten beyond the stage of mental culture in which the verbal discussion of a subject which has been read is of the greatest service in fixing the facts in the mind. This is nothing more nor less than a recitation. Class recitation is preferable to solitary recitation, not only because of the ad-

vantages always to be derived from personal attrition with individuals engaged in the same pursuit, but because of the new ideas brought out in the class-room consideration of a subject. In numbers of instances in the writer's observation, suggestions of the utmost interest and advantage have been derived from the least promising members of his class during such discussions. The recitation plan is far superior to the lecture system because of the opportunity which it gives to the learner to formulate and fix the facts which he has been taught. For the same reason, it is even more to the advantage of the members of a first-aid class if they are given an opportunity to teach the subject to others. If a man possesses much personal pride, the position will put him on his mettle to learn more than his class, and prove a genuine stimulant to study.

All of these methods of instruction have their advantages and all of them have their failings. A plan, to be thoroughly successful, should combine all their good features and exclude all their objectionable points. And yet it is impracticable to devise a plan that shall be equally adapted to every grade of intelligence. There must be at least two grades of instruction, and perhaps three. In the army we have four classes of persons to instruct: 1, Hospital corps; 2, officers of the line; 3, company bearers; 4, all other enlisted men. The second and third classes may be considered in the same category in considering the amount of instruction to be given them, about the same extent of qualifications being desirable in both.

The facilities for the instruction of the hospital corps are greater than for either of the other classes, their residence in the hospital and their more or less constant contact with the sick and injured giving them a certain degree of technique to be gained in no other way, while their freedom from other duties makes it possible for them to give much more time to first-aid study than any other of the four classes.

The company bearer, according to the experience of some medical officers, has been a most unsatisfactory subject for instruction, for three reasons: (1) The fact that through carelessness in selection a poor class of men is apt to be detailed; (2) the frequent changes in details; and (3) the interference of other duties with the hours of instruction. These faults are all usually easily remedied—the first by calling the attention of the company commanders privately to the desirability of detailing good men; I have yet to find the company commander who is not amenable to reason under these circumstances. The second difficulty is also very readily overcome by calling the attention of the post and company commanders to the disadvantage of changes, and by declining to approve of new details. And as to the third objection, post commanders will almost invariably arrange for men on other duties to be present at the hour of first-aid instruction. I believe the company bearer to be an important factor in the first-aid work of the army, and it is hoped that he will remain as a permanent feature. The recent order requiring all enlisted men to be instructed in first aid has had a decidedly stimulating effect upon the company bearers. Realizing that they have the advantage of their comrades in their previous instruction, they are the more willing to push on and keep ahead.

The methods of instruction for the four classes may with advantage be very much the same, differing only in degree. The hospital corps, by daily instruction until qualification is attained, should be pushed forward to an entire acquaintance with the subject. The officers and the company bearers are, as a rule, taught better in weekly meetings, but at separate hours, and at such a rate of progress as each may be capable of.

The method of instruction giving the best results is a combination of the *viva voce*, the text-book, and the

practical demonstration. The subject of each lesson should be gone over orally by the teacher before any recitation is held upon it. The talk upon the subject should be illustrative and demonstrative, and points should be clearly brought out. The lecture, if it may be dignified with that title, should exactly cover the ground of the lesson assigned in the text-book for the next session. To obtain the best results, it will not be sufficient for the teacher simply to read the account of the subject from the book, as is not infrequently done; he must speak in his own language and endeavor to infuse the magnetism of his own personality into his class. Many of the learners will prefer to read the text-book version before the lecture, thus placing themselves in a position to more fully appreciate the comments of the instructor. The next hour of instruction should then be opened with a recitation upon the lesson previously given out. This recitation should not be conducted in a pedagogical style, but with a view not only to ascertain the familiarity of the student with the lesson, but to fix it in the minds of the learners by every available accessory. Charts, drawings, photographs, specially constructed apparatus, and practical demonstrations should all be used whenever they can be applied. The stereopticon is a valuable assistant, but there is a temptation in its use to overdo the matter; it should not be used more than once in four or five hours of instruction.

The great tendency of the instructor in first aid is to fire over the heads of his audience. "There is a fatal facility in the use of technical terms," says Butler, which it is difficult to repress. To present his facts in simple language and to avoid technicalities is the earliest lesson the first-aid instructor has to learn. It is astonishing what ignorance of matters pertaining to the human body and the ills to which it is subject may be found in the most intelligent laymen. It was only the other day that I overheard a discussion upon the reliability of the Scriptures, the argument being finally closed by a man of the highest intelligence, an author and of commanding influence in the community, who triumphantly cried: "How is it, then, that a man has one rib less on one side than on the other?" No technical expression should ever be used until it has been fully and distinctly explained; and, in general, simple Anglo-Saxon nomenclature is better than the Latinized verbosity of the scientific treatise. "Bleeding" is better than "hemorrhage;" a bone had better be "broken" than "fractured;" "breathing" is as good as "respiration;" "bloodless" is clearer than "exsanguinated." Simplicity of diction cannot be sought for too assiduously.

It goes without saying that the elements of anatomy and physiology are an indispensable preliminary to first-aid work. The amount of instruction in this introduction to the subject will vary with the four classes to be instructed. The hospital corps, officers, and company bearers should learn the skeleton to the extent of becoming acquainted with the names, shapes, and locations of all the principal bones and such conspicuous features of them as may be useful in first aid. It will not be necessary for them to learn the structure of the temporal or ethmoid bones, nor to know the tarsus or carpus in detail. But the peculiar arrangement of the bones at the elbow or shoulder or hip should be learned—they should know what the olecranon, the trochanters, and the acromion are, because of their relation to many accidents; and a similar acquaintance with other parts of the osseous structure is essential for a satisfactory comprehension of the emergencies connected with them.

The study of muscles and joints in detail is not needed in a student of first aid. The emergency man will not attempt to reduce any but the simplest dislocations, and individual muscles will play but a very

unimportant rôle in any assistance he may be called upon to render. He should, however, know the general characteristics, purposes, and functions of them both. The nervous system is of comparatively little importance to the first-aid man, and he need study only the first principles of its structure and distribution. He must, however, know the topography of the trunk with reference to the principal viscera, because of the important bearing these facts have on the application of first-aid treatment.

The vascular system is, of course, by far the most important division of the body with respect to first aid study, since treatment of its lesions forms the most important part of emergency work. The physiology of the circulation explains the philosophy of hæmostasis, and the topography, particularly of the arteries, is an essential for the application of proper treatment for hemorrhage. The names of the principal arterial vessels should be learned and their location and some facts with regard to their size and relation to dangerous bleeding. I shall not attempt, however, to give a complete synopsis here of the anatomical and physiological facts essential as an introduction to first-aid study. I have done this in full elsewhere.¹ It is desired to suggest simply the merest outline preliminary to a brief consideration of the best method of teaching the facts.

The bony framework itself is the foundation of all first-aid study, and nothing can be substituted for the human skeleton for this purpose. The best results are to be obtained from a combination of an articulated and a disarticulated skeleton. In the former the mutual relations of the component parts can be shown and demonstrated, while by means of the latter the peculiarities of the individual bones can be shown. The course of the circulation and the location of its component parts, other than the heart, can best be shown by charts, as, except in the rarest cases, it will be impracticable to demonstrate them upon the cadaver, which is the ideal method. Moreover, except with the hospital corps, who become accustomed to death through their ordinary duties, there are peremptory though sentimental objections to the use of any part of the cadaver, except the skeleton. But, while the topography must be obtained from charts, many of the most interesting general facts and much of the morphology can be displayed in the anatomy of the lower animals. The common domestic cat² is a treasure-house of information for the first-aid class. A dog may be even better, if he is larger. It is well to anæsthetize the animal in the presence of the class and to demonstrate the action of the heart and lungs in active movement before life is extinct. If care has been taken that the act of digestion shall be active at the time of the demonstration, a display of the mesenteric lacteals is always received with great enthusiasm by a class. A few remarks upon the similarity and the differences in structure between the cat and the human being are always interesting and clarifying in their effect upon a class. The differences between the various kinds of hemorrhage can be shown by practical illustration, and by opening a vein and an artery at the same time the venous and the arterial bleeding can be actually compared. A muscle or two can be dissected out to show what muscle actually is, together with its general morphology, and the tendons and aponeuroses can be displayed. If the long muscles be taken for demonstration, an excellent showing of muscular action can be given. The biceps, for ex-

¹ "First Aid in Illness and Injury," by James E. Pilcher. 8vo. Second edition, 1894, pp. 322. Charles Scribner's Sons, New York.

² The subject may be studied up with advantage in Gorham and Tower's "Laboratory Guide for the Dissection of the Cat," published by Scribner, or the excellent work on "The Dissection of the Dog," published by Howell, Holt & Co.

ample, may be isolated and the forearm moved by traction upon it, so as to show both flexion and supination. The sciatic nerve can be uncovered and used as an illustration of the elements of the nervous system. The skull can be opened and the undeveloped brain of the cat can be used to demonstrate the membranes and substance of the brain and its relation to the spinal cord. The brain itself can be made to give interest to the comparatively uninteresting topics of brain compression: for this purpose it is well to use two beef brains, one hardened in alcohol to show the form of the brain and its parts; and the other fresh, to show the texture and friability of its substance—an important feature in the demonstration. A glance at ophthalmic anatomy upon a beef's eye may always be used with great advantage to lend interest to a lesson, while the study of the circulation can never be considered complete without a demonstration of the heart's action upon the cardiac organ of a bullock, using, to show the valvular action, either air through the blow-pipe or water through a rubber tube. The interested student of first aid should be advised always to read over in his manual on the subject the topic of the demonstration, both before and afterward, in order to prepare his mind to understand the demonstration and to impress upon his mind what he has been shown.

The elements of bandaging and surgical dressing should always be taught practically. For the ordinary first-aid class the triangular bandage will be ample, but the hospital corps must be taught the application of the roller bandage as well. It is my plan in teaching the triangular bandage, after carefully explaining the theory and practice of the dressing and showing its practical application upon all parts of the body, to divide the class into equal parts, calling them the front and rear ranks respectively. Each member of the class, then, at the word of command, applies each bandage upon the man with whom he is paired; first, each front-rank man applies the head bandage upon his rear-rank man, who then at the word of command reciprocates the act; the rear-rank man then applies the next bandage, and the front-rank man reciprocates—and so on alternately until the entire subject has been thoroughly gone over. This plan is an excellent one to follow in studying the treatment of bleeding, of broken bones, and of wounds. It not only gives each member of the class actual experience in applying treatment, but enables him to see its application in his own person, fully as instructive an experience as the other. What one of us has not learned far more about some malady by observation in his own case than he could have been taught by a thousand lectures and a hundred cases in other individuals?

The treatment of drowning and the use of artificial respiration for other purposes may with great advantage be taught in the same practical manner.

Exercises in the extemporization of dressings are of the greatest importance and contribute greatly to the interest of a class. Each member should be given the opportunity to exercise his own inventive faculty in the origination of such appliances. The amount of ingenuity developed by these practical exercises is sometimes remarkable in the extreme. The suggestions as to materials for dressings, splints, padding, bandages, and the like are often original and valuable enough to instruct the instructor.

Medical emergencies do not usually admit of practical demonstration. The "dummy chucker" does not, as a rule, practise his arts for the delectation of first-aid students, although it might be possible for an instructor whose work brought him in contact with the criminal elements in a large city to find one for the benefit of his class. I considered myself very fortunate when, upon one of my drill hours, a company bearer had an epileptic convulsion in the presence of the de-

tachment. This has occurred but once in my experience, however, and I do not expect it again; and this class of emergencies, including the treatment of poisoning, particularly demands the use of a text-book. It is impossible for a lecturer, however graphic and impressive his delivery may be, to impress these subjects clearly, definitely, and sufficiently by verbal effort alone. They must be learned by careful study and repeated re-reading.

One of the most efficient elements of success in maintaining interest is variety. A pursual of the method already rehearsed would give variety to a lesson upon most of the emergencies considered. But a plan that is of advantage in all cases is to divide the time for instruction into three parts, devoting one part to a brief lecture and demonstration, a second to a quiz and recitation, and a third to litter drill. When either one of the three seems to demand more than a third of the time, any one or any two of them may be dispensed with. Variety may also be obtained by detailing a member of the class to conduct any part of the work, giving him sufficient time previously to enable him to prepare himself for the duty.

The foregoing remarks apply more particularly to the instruction of the first three classes—the hospital corps, the officers, and the company bearers—given by medical officers. The instruction of the fourth class—the enlisted men in general—must necessarily be much less complete, both on account of the lack of knowledge and experience upon the part of the line officers who are to conduct the instruction, and the lack of capacity upon the part of the men who are to receive it. The amount of instruction actually given to the companies will necessarily vary according to the personality of the instructing officer. But enough for the purpose may be presented in five lectures upon the following subjects, each occupying a full hour:

1. The Human Body (the skeleton and the circulation in particular).
2. Bandages and Dressings (the triangular bandage in particular).
3. Wounds and Bleeding.
4. Broken Bones.
5. Insensibility (drowning in particular).

These subjects need not be presented in a consecutive series, but the lecture hour for several occasions succeeding each lecture could with much advantage be devoted to going over the matter of the lecture with the men and fixing the points in their minds. Wounds, for instance, should not be ventured upon until the bandages and dressings have been mastered.

The question of impressing the facts retentively upon the remembrance of the men is a most difficult problem. Demonstrations of practical anatomy are, of course, out of the question, and it is usually impracticable for the skeleton to be used in teaching the bones. Here pictures must come in. Charts may be issued to the companies for general demonstration. It is impracticable to expect them to study first aid from a comprehensive text-book, for many of them have not the intelligence to comprehend the subject upon reading, and a still greater number have not the patience to try it. In this case it seems to me that we should go back to the method of the untutored savage, which should be within the comprehension of the least intelligent soldier, and teach by picture writing. Something of this kind has been attempted in the German triangular bandage of Esmarch, which has been almost ruined in the peculiarly wretched American imitation. The St. Andrew's Ambulance Association of Scotland produces a triangular bandage which is a great improvement upon all others, and in it has been attained the climax of pictorially treated bandages. But these are unsatisfactory as means of instruction, both because of paucity of information and their de-

iciency in permanence. It is impossible upon a triangular bandage to illustrate, even with very small representations, a tithe of the points needed to impress the mind of the soldier, and the crumpling and soiling of the bandage in the hands of its possessor will easily render it too illegible for consultation—an objection which will grow with the enthusiasm of the frequently perusing soldier.

Admitting the value of the handkerchief within its limitations, *i.e.*, the illustration of only a few of the principal procedures in which it is applicable, we should go much further. The need can be supplied by a little book containing pictorial representations of all the important facts of first aid, with as little reading-matter as possible. After this idea had been quite fully developed in the writer's mind, his attention was called to the "Album für Krankenträger" of Dr. Ruhlemann, a surgeon in the army of Saxony, which had been used with very great success in the German army. Dr. Ruhlemann's book is directly in the line suggested, but with the pages a trifle too large and the illustrations very poorly executed. A little book upon this plan is now in active preparation for the American press, and in it an effort has been made to do away with the objectionable features of the German work, and to present a little manual clearly American in its characteristics as well as in its language, and arranged in the order suggested as the most desirable one for the instruction of the enlisted force.

Officers of the line may with much advantage, in transmitting first-aid instruction to their commands, utilize as far as practicable the features for interesting and stimulating the attention that have been presented by their own medical instructors, and add to them such other features as their own ingenuity and enthusiasm may suggest. Competition is always an important stimulus to work among men. The enthusiasm which is awakened by competitions of any kind, from baseball to rifle practice, may well give us pause in our consideration of methods of instruction in first aid. The writer saw a Canadian judge and an officer of one of the Massachusetts courts, on the high seas and near the coast of France, where it was impossible for either to learn anything of the merits of the case, warm up to the point of personal collision over the respective merits of *Valkyrie III.* and the *Defender*. The quality which will, at the close of the nineteenth century, bring to the point of the duello two gentlemen of the practical Anglo-Saxon race, because of the rivalry of a couple of racing sloops, would certainly seem to be an advantageous addition to first-aid instruction. Competition may be introduced into first-aid military work by the institution of inter-company, inter-regimental, inter-department or brigade first-aid competitions, and the establishment of a grand periodical competition for the championship of the entire army. Each company being divided into little squads of four men, graded by a competitive examination, the winning squad should be entitled to compete for the championship of the post or regiment. The champions in this competition should then be assembled at some central point in the department, considering the army, or the brigade, considering the national guard, to compete for first place in the department or brigade. And, finally, at such intervals as may be desirable—annually, biennially, triennially, or even quadrennially—the department or brigade champions should be given an opportunity to compete at some central point for the championship of the army or State. A trophy, consisting, perhaps, of a bronze figure in armor protecting a wounded comrade with a shield bearing the red cross, might with advantage be the chief trophy, the custody of which would be awarded to the company furnishing the victorious squad. Similar smaller designs could be awarded to the companies furnishing

the department or brigade champion, and still smaller ones for the champion squads of the regiment or post. The writer has often observed the advantage of competition in drilling his own detachment. When the day is depressing and the men seem a little sluggish, the dummy wounded are often instructed to seek their own location, and then, after informing the detachment that the design is to see which squad will bring in its man the most expeditiously, carefully, and safely, the command is given, "Search for wounded." At the first suggestion of an approaching competition an alert expression supplants the sluggish one, the eyes brighten, and eagerness characterizes every attitude. The response to command is instant and their execution of the order characterized by a degree of efficiency obtainable in no other way. It is believed that the extension of the feature of competition to the entire army in the manner suggested will be of incalculable benefit in promoting the efficiency of the service.

First aid in illness and injury is an active, living issue of a concrete kind, that can be appreciated by every one, whether in the military service or in civil life. It is, then, of the highest importance to determine the methods of instruction from which the greatest efficiency of first-aid service can be derived. From our study, we have determined that in military practice there are two principal grades of instruction:

1. Instruction of the officers of the line, the hospital corps, and the company bearers, given by medical officers.

2. Instruction of the enlisted soldiers in general, given by officers of the line.

The best method of instruction is a combination of the lecture, the demonstration, and recitation from a text-book, neither of the three being sufficient without the accompaniment of the other two.

The best instruction is characterized by extreme simplicity of diction and the avoidance of all technicality in language.

The best instruction is progressive in character, beginning with anatomy and physiology, and advancing to bandages and dressings, and then to emergencies proper.

The class-room work of the first grade is advantageously supplemented by home study of a first-aid text-book, and, when desired, it may be complemented by the use of a pictorial remembrancer.

The class-room work of the second grade may best be confirmed and fixed by the use of a pictorial remembrancer, a copy of which should form a part of the equipment of every soldier.

Interest in the work of both grades should be stimulated in every possible way, especial attention being devoted to the development of interest in the second grade, a series of public competitions being suggested, the champions to be rewarded by the custody of suitable trophies.

By the methods and with the stimulus thus provided, it is believed that every member of the military forces of the country, including the army, the militia, and the national guard, may become qualified to cope temporarily with any relievable injury that may occur on the march, in camp, or on the field of battle. War can never become benevolent, nor can bullets be transformed into white-winged messengers of peace; but the horrors of war can be enormously mitigated, the sufferings of unnumbered victims assuaged, thousands of useful lives saved. It has been stated that after an engagement more deaths occur from delay in applying proper treatment and from exposure on the field than from the fire of the enemy. It is the function of first-aid instruction to avert all these, and by the magnificent organization now established to diminish the

mortality of future campaigns, to achieve victory at a smaller cost, and to dull the teeth of the dogs of war.

And in time of piping peace, no less than in days of raging war, will the good effects of the system be felt. The thousands of men that every year go out from the army and the national guard into the daily life of our country will carry with them the ability to succor the suffering and rescue the perishing, and, by the aid which they will afford here and there throughout the entire nation, will accomplish an amount of good, by the side of which even the splendid philanthropy of first aid upon the battlefield will seem to be insignificant in comparison.

REPORT OF CASES IN ABDOMINAL AND PELVIC SURGERY.

BY A. H. CORDIER, M.D.,

KANSAS CITY, MO.

Gastro-Jejunostomy with the Murphy Button.—A man, aged sixty-six, some eight years ago had an attack of hepatic colic lasting several hours, followed a few days later by a jaundice persisting three or four weeks. He soon regained his former good health and remained so up to two years ago, when he had another colic attack not so severe and not followed by jaundice. One year ago he began to have more or less pain in the region of the stomach, or rather, as he termed it, an uneasiness after eating. After two or three months of this uneasiness, he began losing flesh and had occasional vomiting spells. No blood was vomited at any time. At the time I first saw him, March 1, 1895, he had not been able to digest or retain much solid food for several months, and was greatly emaciated from his former weight, two hundred and forty pounds. He now weighs only one hundred and thirty pounds. His appetite was fairly good, and liquid nourishment was taken with relish and fairly assimilated. Solid food caused pain and nausea until relieved by vomiting. On examining him I found that he was greatly emaciated, had a "swarthy" look not exactly that of a malignant cachexia. Pulse and temperature were normal. Examination of the abdomen revealed a greatly dilated stomach, and its peristaltic action could be plainly seen through the parietes. It was painful on pressure only in the region of the pylorus; here an unnatural sense of resistance could be distinctly made out, covering an area about as large as the palm of the hand or smaller.

A test meal examined revealed an absence of hydrochloric acid. A diagnosis of a malignant stenosis of the pylorus was the most acceptable theory to me, yet a non-malignant stricture had been made out by a good diagnostician before I saw the case.

A tonic of strychnine and iron was given, and nutrient enemata were ordered four times in twenty-four hours. Under this regimen he gained eight pounds in a month.

A median incision four inches long was made, extending downward from one inch below the xyphoid cartilage. A loop of jejunum was pulled into the incision. After pushing the omentum to the left, a "puckering-string" stitch was put in the convex surface, the gut was incised, and one-half of the Murphy button—the larger piece (one inch in diameter)—inserted. The stomach was pulled into the incision and a similar opening was made in its anterior wall about four inches from the pylorus, and the other half of the button placed in position and securely fastened by pushing the two halves together. The approximation was perfect. A running Lembert stitch was put in on one side to give additional security against any accident that might occur from vomiting; besides, the

walls of the stomach were thickened from long and constant peristalsis. The patient left the table with a pulse of 90. He vomited for the first time ten hours after the operation, a large quantity of bile being thrown up. Two days later he had a similar attack of vomiting. The bowels moved on the second day. There was no distention at any time.

On the twelfth day I could feel the button distinctly, near the tenth rib. It was freely movable and had evidently completed its work and left its moorings at that time. Eggs, milk, ice cream, soft toast, rare beef-steak (chewed and the juice swallowed) formed his dietary at the end of two weeks.

On March 1, 1896, the man had not found the button, but wrote me that he thought it had passed some time during his three weeks' stay at the hospital. He has continued to gain in weight and strength, is free from pain, vomiting, or other symptoms pointing to malignancy, and I trust that my probable diagnosis of malignancy may prove to be wrong.

Sterile Echinococcus Cyst.—A woman, aged forty-six, the mother of several children, was first seen by me on September 10, 1895. Some seven years ago she noticed an enlargement in the region of the gall bladder. She at that time had several paroxysms of pain in that locality. During the interval from that time up to the present attack she had had no severe pains, but more or less uneasiness in the enlargement.

Some three weeks ago, after a long, tiresome ride in an uncomfortable vehicle over rough roads, she was taken with pain in the right hypochondriac region. A fever, continuous in character, of moderate intensity (100° to 102° F.), began about this time; the pulse was 90 to 100. The appetite was lost and in its stead was a loathing of all nourishment.

Examination revealed a growth the size of a fetal head, smooth, globular, painless, semi-fluctuating, occupying the right hypochondriac, renal, and umbilical regions. The abdominal walls moved freely over the growth. There was dulness all over the growth and continuous with normal liver dulness. At the lower border of the growth and in the median line two inches below the umbilicus, the globular or pear-shaped gall-bladder enlargement could be made out, movable on a stalk or stem, seemingly about the arc of a circle six inches in diameter.

On September 13, 1895, an incision was made in the right semilunar, from a point an inch below the free border of the ribs, extending downward three inches. The liver was cut directly down upon. Evidences of localized peritonitis existed over the surface of the organ in a few places. The gland was smooth and enlarged. Exploratory punctures were made, but no pus or other fluid save blood was found. The gall bladder could be easily made out, as the enlargement in the median line spoken of above. This incision was closed and another made directly over the gall bladder, two inches below the umbilicus. This opening was only one inch in length, and in it the gall bladder was stitched with one suture at its fundus, the wound in the parietes was packed with gauze, and the patient was put to bed.

There was absolutely no reaction following the operation. On the third day I incised the gall bladder. A large quantity (four ounces) of thick, clear, albuminous fluid escaped. Not wanting to remove the stones (which had been diagnosed at the operation) at that time, lest the adhesions be disturbed, I decided to wait a day longer. At this time (four days after the operation) I removed one hundred and twenty-five stones, the largest weighing thirty grains (a large stone, as gall stones are very light in proportion to their bulk). No bile escaped from the gall-bladder fistula, showing that the cystic duct was yet occluded. At this time I made another exploratory puncture in

the enlargement, recognizing that there existed adhesions over its surface and that no loop of intestine was in front of the liver, thus making the punctures safe. No fluid but blood was obtained by this tapping.

The patient died three weeks after the operation from exhaustion, the stomach refusing to take or retain any nourishment.

There are several features in this case worthy of comment. The large number of gall stones, with an entire absence of hepatic colic and absence of jaundice, can be explained only by the supposition that none of the stones ever passed into the common duct, or, if they did, they passed without much constriction or pain. The absence of bile in the gall bladder is easily understood, with the cystic duct occluded as it was by the stones in this case. The late attack, with pain, tenderness, and fever, was due to infection in the gall bladder. The large, smooth, liver mass was due to the bulging of a cyst from its under surface or deeper structure. The rapid development was deceptive, and the mass was made rapidly prominent at the expense of the absorption of the adipose in the abdominal parietes. The cyst, being in an old person (ecchinococcus developing usually in the young), had evidently developed earlier in life, and the ecchinococci, dying, left the cyst sterile; its contents, instead of having a specific gravity of 1.015 with no albumin and abounding in sodium chloride, was so changed by this sterility that its specific gravity was 1.032 and albumin was present (possibly due to presence of blood). The absence of hooklets can also be readily understood as being due to the sterility of the cyst's contents.

Pyonephrosis; Nephrotomy.—A lady, aged forty-six, the mother of three children, was taken down some eight weeks ago, having had "bad health" for several months before. She had been having what was called cystitis—frequent desire to urinate and much dysuria. Her bladder had been washed frequently and treated locally by instilling various solutions recommended for bladder inflammations, but all to no avail, as she continued to get worse, passing large quantities of pus (pyuria).

At the time I first saw her, with Dr. Porter, she was thoroughly septic; temperature varying from 100° to 105° F.; pulse, 120 to 140; anorexia, night sweats, passing large amount of pus in urine that was very irritating and offensive. The urine was ammoniacal or strongly alkaline. On the side to the right of the umbilicus and extending from the last rib to the crest of the ilium and into the loin was a well-marked enlargement, globular in shape, smooth to the touch, fixed, and very painful on manipulation.

This tumor had been gradually increasing for several weeks, and had not at any time diminished perceptibly. The patient presented no evidence of jaundice or other conditions pointing to gall-bladder or liver involvement. This tumor was the size of a good-sized cocoon. Taking the history of bladder trouble, rebellious and protracted, and with pus constantly in all urine, and the history of sepsis and a gradual enlargement in the region of the right kidney, a diagnosis of pyonephrosis was made, and an early operation was advised.

Operation was performed October 4, 1895. A hurried nephrotomy was performed, making the opening well posteriorly to promote drainage; the kidney was incised, a drainage tube was inserted, and gauze packing was introduced. A more extensive operation was not advisable, owing to the extreme septic condition of my patient. These cases stand operation and anaesthetics badly. The kidney abscess drained fairly well for a few days, the pulse, temperature, and appetite improving very much. The discharge then began to diminish, and with this the old symptoms of sepsis

returned. I then decided to do either a nephrectomy or a more extensive nephrotomy. At the operation the latter was decided upon, owing to the feeble condition of the patient and the extreme difficulty likely to be experienced in delivering the kidney and ligating the pedicle. The old incision was carried downward and forward to near the anterior spine of the ilium, and the whole length of the enormously enlarged organ was exposed on its convex aspect. The kidney was incised its whole length and each compartment of pus was broken into with the finger, during which process a most terrific hemorrhage took place, filling the wound faster than my assistant could sponge it out. This part of the operation was quickly completed, and the opening in the kidney was snugly packed with gauze to control the bleeding. The wound was left open in the overlying structures.

The patient suffered very much from shock and loss of blood, and was put to bed in a very weak state. One-tenth of a grain of strychnine was given during the operation, which lasted only fifteen minutes; the foot of the bed was raised, hot applications were made about the body, and hot milk and whiskey enemas were given. During the night she lost considerable blood, and at my visit next day I found her calling for more air and giving evidence of acute anæmia and profound shock. Pulse, 144; temperature, 96° F.

Twelve ounces of a sterilized normal saline solution were injected into the cellular tissue of the posterior surface of the thighs. Within an hour this resulted in reducing the pulse to 116 beats. The gauze packing was removed at the end of forty-eight hours, and the cavity was irrigated with an iodine solution and repacked. Nutrient enemas were continued each four hours until her stomach was able to retain nourishment, the wound being treated as above daily. Nourishing food, iron, strychnine, were given right along day and night.

January 15, 1896.—She improved for a few weeks following the last nephrotomy, but again lapsed into her old septic condition, with a pulse daily running up to 120 to 140, temperature 101° to 103° F., the drainage diminishing all the time. At this date I decided to make an effort to remove the kidney. The overlying tissues were infiltrated and indurated. The kidney was as large as a cocoon and extended below McBurney's point upward beneath the liver. An incision was made along the line of the last operation, but extended farther forward from the lower end of the old scar. Another cut was made near the upper end of the horizontal incision, the direction of which was parallel with the last rib. This increased the working-limit considerably. The kidney was separated from its firmly adherent surroundings, down to the ureter and vessels. The pedicle was so deeply situated and the kidney so large that it was impossible to get a ligature down to it. I thought I would have this difficulty to encounter, and had my Koeberle serre-nœud and wire ready. The wire was tightened about the pedicle and the kidney cut away with scissors, leaving a good pedicle button; no loss of blood. The instrument was permitted to remain for three days and was then removed, without bleeding. Her convalescence was uneventful.

Vaginal Hysterectomy for Cancer in the Pregnant Uterus.—The patient, aged thirty-two, eleven months ago gave birth to a full-term child. Nothing unusual occurred during her confinement or convalescence. Three months ago she had quite a profuse hemorrhage, with a continuance of the flow from that time up to the present. I saw her three months after the first bleeding. She had been losing flesh and strength very rapidly. An examination revealed a bilateral cervical tear, and on both lips of the cervix was a large cauliflower-appearing surface that bled

easily to the touch. The uterus was the size of a small coconut and very much the shape of a pregnant uterus; but as the woman presented not one of the subjective symptoms of pregnancy and had not menstruated since her last confinement, eleven months ago, the idea of pregnancy was quickly dismissed, as the all-important point in the diagnosis related to the question of malignancy. A piece was cut from the growth and examined by myself and by two other pathologists, all agreeing that it was malignant.

On October 29, 1895, I performed a vaginal hysterectomy, using, as I always use, the Price hysterectomy forceps. It was somewhat difficult to pull the uterus through the vaginal-vault opening, but, owing to the elongation taking place from the traction on the cervix at the expense of the width of the organ, it was delivered and the operation was completed in twenty minutes. At the end of thirty-six hours the forceps were unlocked and a few hours later removed. The patient's temperature never reached the hundred point, the pulse remaining under 80 during her entire convalescence. She left the hospital on the nineteenth day.

This is a very rare condition, occurring about once in two thousand cases of pregnancy. In twenty-seven cases tabulated by Vanderveer,¹ five women died during labor undelivered and nine died during the puerperal period; in three cases the results are not mentioned; ten patients recovered—a mortality to mothers of sixty per cent.

Another author reports three hundred cases of cancer of the uterus complicating pregnancy, with a mortality of fifty-two per cent. Abortion occurs in thirty-five per cent. of cancerous pregnant uteri. The mortality to the mother in abortion is very high. In twenty-five per cent. of cases dying undelivered the fatal result was due to a retained putrid fetus, shock, or exhaustion. Post-partum sepsis comes in for a big percentage in the mortality. Rupture of the uterus occurs frequently. Rapid spread of the growth, owing to increased circulation during pregnancy, takes place. Most of the few mothers surviving delivery die within three months. Only thirty-three per cent. of children are born alive, and twenty per cent. of these die within a few weeks. A large percentage of the few living children is left motherless.

Tetanus.—Dr. E. F. Trevelyan reports a single case of cephalic tetanus treated by injections of antitoxic (antitetanic, Roux) serum. This was without result, although two successful cases have been reported by Caretti and by Einstein and Buonati. This disease is also known as tetanus hydrophobicus, owing to the pharyngeal spasm induced by attempts at swallowing; tetanus paralyticus, as proposed by Klemm, to emphasize the importance of the facial paralysis; and bulbar tetanus, to accentuate the fact that bulbar symptoms are so frequently present. There is, however, no real difference between cephalic and ordinary tetanus, as is shown by the fact that the muscular spasm tends to become general in both; in fact, it is only a difference of mode of ingesta, the former resembling more closely experimental tetanus. Failure in this case may have been due to an insufficient quantity used or to the use of the warm water in dissolving the desiccated serum. This is the third instance in which the author has observed the use of the remedy—in one the Tizzoni-Cattani serum was employed—and in all it did not appear to have the slightest effect upon the disease.—*British Medical Journal*, 1896, No. 1832, p. 321.

Progress of Medical Science.

The Blood in Tuberculosis of the Bones.—Dr. John Dane, of Boston, has studied the condition of the blood in cases of articular and osseous tuberculosis. The results of his observations are published in the *Boston Medical and Surgical Journal*, and are summarized as follows: (1) Most cases of tuberculosis of the bones and joints do not decrease the number of the red corpuscles in the blood. (2) They do, however, affect the percentage of hemoglobin, giving rise, in fact, to a mild degree of chlorosis. (3) The leucocyte count seems to bear no direct relation to the temperature. (4) High counts, especially in hip disease, point to the probability that there is or shortly will be an abscess formation; but low counts do not preclude the presence of abscess, especially in cases of long standing. (5) When, in connection with a low leucocyte count an abscess is found to exist, the pus from it is sterile, and the case is generally one of long standing. (6) In the presence of an abscess, a low leucocyte count generally indicates the absence, and a high count the presence, of a secondary infection with pyogenic organisms. (7) Cases in which, at the primary operation, the pus has proved sterile, show an increase in the leucocyte count when the wound becomes infected with pyogenic organisms. (8) High leucocyte counts do not always affect the differential count. (9) Cases with a traumatic origin are generally accompanied by a high leucocyte count and run a more severe course. This is especially shown in cases of hip disease. That more of the cases which entered with a developed abscess did not give a definite history of trauma is due no doubt to the fact that the length of time the disease had been progressing had caused a lack of accurate detail at the beginning being remembered.

Management of Pregnancy with Nephritis.—Dr. Mynlieff (*Der Frauenarzt*, January 1, 1896) says that when a woman with chronic nephritis becomes pregnant the induction of abortion is indicated on account of the immediate peril of the patient, which increases as pregnancy advances, the certain continuance of the morbid process in the kidneys, the great tendency to flooding and abortion, and the small prospect of the development of the fetus up to term. When the physician is called in when pregnancy is advanced, the induction of premature labor may be undertaken at the time which seems most favorable for saving the life of the fetus. The history of previous pregnancies must be duly considered, and if it is found that the fetus tends to die at a certain date in pregnancy, that date must be anticipated. In any case the life of the mother must be considered first; hence immediate interference is usually the safest course. The same principle is often best for the fetus when viable, as it may die suddenly earlier than in previous pregnancies.

Incompatibility of New Remedies.—Moerck points out that trichloride of iodine is decomposed by alcohol and partially by water; the aqueous solution liberates iodine from iodides; ammonia added to it forms the explosive iodide of nitrogen; reducing agents liberate the iodine; and many organic bodies, among others the fatty oils and alcohol, decompose it. Hydroxylamin hydrochlorate is very unstable and readily forms explosive mixtures; it is a powerful reducing agent. Alkalies liberate the base, which is unstable and explosive.—*American Druggist and Pharmaceutical Record*.

The Doctors in France number 17,500. Four hundred and fifty die each year and 650 new ones are turned out by the universities.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 5, 1896.

"A PLEA FOR A SIMPLER LIFE."

SUCH is the title of a small volume by Dr. George S. Keith, of Edinburgh, in which he seeks to point out some of the evils which, he holds, have arisen from the two opposite lines of medical practice during the past century. A complete revolution has taken place in the practice of medicine within the last sixty years. Formerly all the common diseases were ascribed to overaction, and the remedies were bleeding, vomiting, purging, sweating—in fact, depletion in its most violent forms. A fashionable London physician began teaching that disease was due to a weakened action of the functions and the body needed "setting up," *i.e.*, stimulating and tonic medicines and plenty of good food and drink. This system grew to maturity in a short time and was carried to as great extremes as the other.

Dr. Keith's observation of different methods of treating disease in the various parts of Europe as well as in the East caused him to lose faith in the "depletory system" then practised in England. Dr. Keith relates his personal experience with calomel and aperients, which influenced him further to doubt the efficacy of drugs. Patients wish immediate relief, and something must be given, though one often gets more credit for bread pills than for anything stronger. The aphorism of Hippocrates, "*Melius remedium dubium quam nullum*"—"Better a doubtful remedy than none"—has done much harm. "Better no medicine than a doubtful one." The doubtful medicine may obstruct nature instead of aiding her, and the physician may never know what the natural course of the disease might be. For instance, it is the almost universal custom to administer an aperient when called to a case of scarlet fever. The doctor is usually called in the second stage of the disease, when the poison which has been previously absorbed is being thrown off by the skin and mucous surfaces of the throat and pharynx. It seems natural that an aperient, by setting up intestinal irritation, will interfere with the action of the skin and throat and make the case much more severe than it would be otherwise. Dr. Keith recommends the giving of nothing stronger than milk for three weeks after the disease has made its appearance. When disease attacks the body, the appetite usually fails. Nature usually indicates in this way the course to be followed. There is a reserve fund of nourishment

laid up in the body in the shape of fat and tissue which can be drawn upon during disease, when the digestive organs require a rest. The propriety of giving or withholding food depends entirely upon the condition of the digestive organs. "The physician should always have a dread of giving too much as well as too little." "The doubtful remedies which, according to the new axiom, are to be avoided in states of disease are medicines, alcoholic stimulants, and food; and nature's methods which we advise to be substituted for them, or rather to be allowed full play without them, are rest—not forgetting rest to the stomach—warmth, or, in rare cases, cold; a free supply usually of water and always of fresh air, and sufficient time for the organs to recover their ordinary working-powers, and especially for the nervous system to make up its waste. In short, we must fall back on the old and much forgotten *vis medicatrix nature*."

The author says that the means commonly employed at the present time for the cure of many diseases are precisely those which are, when used improperly, the causes of the same diseases, *i.e.*, food and stimulants. "If a healthy person takes too much carbonaceous food the excess is for a time set aside in the form of fat, or the secretion in the liver of bile is unduly increased, the blood gets carbonized, languor and discomfort come on, appetite fails, and a chill followed by irritation of the stomach ends in a bilious attack. This with enforced starvation clears off the superabundant carbon and leaves the sufferer in a healthy condition. When the excess is animal food, this may go on for years, and if the individual is of sound constitution he may dispose of twice or thrice the quantity of flesh food that is required by his system. The kidneys usually give out first, or the blood becomes loaded with animal matters and these are deposited in various organs in the form of fibrin, which hardens and destroys more or less of their substance and their functions."

Dr. Haig has proved by recent investigation that uric acid in the blood destroys its red globules and induces anæmia, for which good "red meat" has been considered the fittest cure. In experimenting on himself he took a certain quantity of beef tea as an equivalent for a certain number of grains of uric acid. He shows that iron is useless, so long as it is given with red meat. The most white-faced family, Dr. Keith said, that he ever saw was a family of six who had at least two full meals a day of beef and mutton. The evils of food excess are much aggravated if at the same time alcohol is taken.

The author writes: "In my younger days, in the twenties and thirties, the food of the working man and also of the upper classes was simple and good. It consisted mostly of milk, eggs, fish, oatmeal, potatoes, and a few other vegetables. There was no baker and no butcher in the parish, and there was no doctor within five miles. The sanitary state of the houses was worse than now. But with the good food there was not much general sickness. By and by times changed; white bread and flesh came into the market, and along with these luxuries came the doctor. The improved sanitary condition should have led to a

healthier state." As to flesh the author says: "The animal makes a perfect body from vegetable matter pure and simple, but the phosphates go to form the skeleton and in the muscle which we eat they are conspicuous by their absence." Simple and restricted diet is more necessary in advanced life than earlier, and stimulants do more harm then than formerly.

"If when in good health we took only the food necessary for our comfort and work instead of working the stomach to the utmost and helping it when it flags with dainties, drugs, and stimulants, we would have much more pleasure from our meals and a longer continuance of strength and health. If we could eliminate from the old system of cure a large amount of depletion, and from the new a larger amount of the feeding and physicking, we would come nearer to nature's mode of preventing and curing disease and we would find that prevention would be the larger element; the need for the other would be well-nigh extinguished."

OUR SELF-PRESCRIBING PATIENTS.

To such as have studied the causes of the present decline in professional work it becomes a serious question whether there are not other elements than those attributable to stringent business relations that explain the condition. While the science of medicine has made great progress in the methods of diagnosis and treatment, the physician finds that his vocation, although more honorable and useful, is really less remunerative, and his legitimate practice is proportionately curtailed. There is no less sickness in the world, but the number of patients has markedly decreased. In fact, the sick ones are inclined to get the better of the doctor and to act more or less independently of his direct ministrations. It is not difficult to understand why this is so, when we consider the vast number of persons who willingly yield to the growing habit of prescribing for themselves. This tendency is fostered by the belief, in the majority of cases, that such prescribing is tacitly sanctioned by the profession itself by the use of many of the legitimate remedies so frequently ordered for the relief of the more common ailments. There is a very reasonable foundation for this conviction, and its responsibility rests more or less on the prescriber himself. At the bottom of the whole business is the prevailing practice of delivering private clinical lectures to the patient on the nature, extent, progress, and outlook of his malady, and the indications for the use of special drugs in the treatment of certain conditions. While this may give evidence of remarkable learning on the part of the medical adviser and may help for the time being to establish his methods in the confidence of his client, it too often educates the recipient into the presumption of thinking and acting for himself. The most superficial knowledge is all that is necessary to this end, and, easily persuading himself that he has a repetition of the malady of which he has had such an authoritative opinion, he either repeats the prescription at will or purchases his former remedy in open

market at the counter of the obliging pharmacist. Quinine, phenacetin, salol, morphine, pepsin, the mineral laxatives, and a host of other much-used medicines are given the currency of indispensable household articles. To such persons a diagnosis is a useless refinement, it being sufficient for their special purpose that their physician has given explicit directions how to use the supposed harmless remedies under what the patient believes to be similar circumstances. Not only this, but the remedy is freely prescribed to all his friends who are willing to trust to the blind chances of having a like ailment.

With shame be it said that very many of the pharmacists, far from discouraging such practices, not only willingly abet them but offer special inducements to purchasers by peddling the favorite prescriptions of well-known physicians. These drug sellers, for they deserve no more dignified title, do not prescribe themselves, but are willing to recommend the prescription of another, charging a round price for the trouble of dispensing it. When it is understood that the physician knows of this, it is not difficult to explain why so few prescriptions are written and why so many prescribers deal out their own medicines.

Aside from the purely business aspects of the question, this inconsiderate self-prescribing is in the highest degree detrimental to the community at large in stimulating an unnecessary consumption of drugs, in the formation of habits which eventually undermine health, and in directly jeopardizing life by the loss of valuable time in the prompt recognition and scientific treatment of many of the dangerous and insidious maladies of which the ordinary patient has no possible knowledge. The profession should always be ready with any information tending toward the prevention of disease, but any attempt directly or indirectly to teach therapeutics is fraught with untold evil to the giver and the receiver. The more the patient is kept in ignorance of the remedies prescribed, the better for him, and certainly, under the circumstances already named, the better for the prescriber. The physician is never called in consultation with his patient, as the very nature of the case precludes the necessity of more than one opinion. The moment any argument is allowed on this point all proper respect for purely professional opinion is lost. This is one of the results of selling the birthright for a mess of pottage. The lesson is one which many of the too-obliging practitioners can take to heart.

The Health Department of Greater New York.—

According to the proposed charter of Greater New York, there will be but one health commissioner, who may be appointed or removed at pleasure by the mayor. The main office of the department will be on Manhattan Island, but there will be a branch office with a deputy commissioner, a register of records, and a sanitary superintendent in Brooklyn and possibly in other boroughs. The bureaus of the register of records and of the sanitary superintendent will remain as at present constituted.

THE PATHOGENICITY OF THE DIPLOCOCCUS LANCEOLATUS.

THAT the presence of a micro-organism is not necessarily an indication of the existence of disease cannot be better illustrated than by the varying behavior of the diplococcus lanceolatus, or the pneumococcus. This organism, as is well known, is often to be found in the mouths of apparently healthy individuals, presumably giving rise to diseased conditions when the usual relation between its virulence and the bodily resistance is changed—either the former increased or the latter diminished, or both of these conditions are operative. Other organisms, it is true, may also give rise to pneumonia, but the capsulated diplococcus is the most common exciting factor.

It is generally recognized that the pneumococcus is responsible for many of the complications of pneumonia, as well as of a number of independent disorders. This organism is possessed of pyogenic properties, as some of the conditions referred to are further attended with suppuration, the pus being characterized by its viscosity, plasticity, and greenish color.

Simple uncomplicated pneumonia must be viewed as a purely local process in the majority of cases, although a number of observers have succeeded in finding pneumococci in the blood. That generalized infection does not take place more commonly is to be attributed to a relative immunity on the part of human beings. In order for such infection to result—that is, for the pneumococcus to undergo multiplication in the blood and to exercise pathogenic activity—either the micro-organism must possess increased virulence or the patient must manifest congenital or acquired predisposition, or contra-immunity. Cases in which the conditions just named prevail are so uncommon that an observation recently recorded by Schabad (*Centralblatt für Bakteriologie*, No. 25, 1896) seems for this and other reasons to be of unusual interest.

A man, forty-five years old, was suddenly seized with chill, fever, cough, and expectoration, together with pain in the right side of the chest. On the second day he complained of pain in the right hip-joint and on the fourth day also of pain in the left knee-joint. Physical examination made on the sixth day showed the area of cardiac percussion dulness to be increased toward the left, while the heart sounds were obscure, the pulse was frequent, and the vessels were atheromatous. Dyspnea was pronounced and the percussion resonance over the upper lobe of the right lung was impaired, while the breathing was bronchial and subcrepitant râles could be heard. At the base of the left half of the chest in the axillary region pleural friction sounds were audible. The temperature was moderately elevated. Inoculation of agar tubes with blood obtained under suitable precautions resulted in the development of pneumococci, which in turn yielded typical cultural and pathogenic reactions. The case terminated fatally and post-mortem examination disclosed the following conditions: Acute fibrino-purulent pericarditis; beginning parenchyma-

tous and fatty degeneration of the heart; atheroma of the aorta; chronic pleurisy on the left and acute pleurisy on the right; croupous pneumonia involving the upper lobe of the right lung in the stage of gray hepatization with suppuration; acute purulent peritonitis; cirrhosis of the liver; chronic hyperplasia of the spleen; fatty degeneration of the kidneys; purulent coxitis on the right and purulent gonitis on the left. The pus from the joints from the abdominal cavity and from the pericardial sac was thick and yellowish, with a tinge of green. Smear preparations and agar inoculations from the pneumonic lung, from blood from the heart, from the splenic pulp, from the pericardial and the peritoneal exudates, and from the pus from the joints all disclosed the presence of pneumococci. In some of the cultures the bacterium coli commune also developed.

News of the Week.

Drs. L. D. Bulkley and G. H. Fox, of New York, were among the visitors registered at the Carlisle meeting of the British Medical Association.

The Medical Service at the Paris Exposition.—Dr. Gilles de la Tourette has been appointed physician-in-chief for the world's fair of 1900 in Paris.

The Brewing of Ale is on the increase in Great Britain, a tax having been paid on over one million barrels more this year than last.

"Appendicitis as it Affects Life-Insurance Risks."—The author of the paper with this title, which appeared in a recent issue, was Dr. Albert Wood, not Woods, as written.

The Fourth International Congress of Hydrology, Climatology, and Geology will be held at Clermont-Ferrand, Puy de Dôme, France, September 28th to October 4th. The general secretary of the congress is Dr. E. Fredet.

Dr. Besnier will be the president of the next International Congress of Dermatology, which will be held in Paris in 1900 during the exhibition year.

Typhoid Fever in New Haven.—A small epidemic of typhoid fever prevails at New Haven, sixty-nine cases having been reported during the last few days of August. Most of the cases have been traced in their origin to milk supplied by one dealer.

The State Commission in Lunacy.—According to a telegram from Albany, Dr. Carlos F. MacDonald, president of the State Commission in Lunacy, has resigned, the resignation to take effect the last of this month. Dr. Peter M. Wise has been appointed by Governor Morton to succeed him.

A Limited "Kur."—The park commissioners have given permission to the members of the Kneipp-Verein to walk barefooted upon the grass of certain portions of Central Park, between six and eight o'clock in the morning. This privilege is granted for one week only.

The Semi-Centennial of Anæsthesia.—It is proposed in France to celebrate during the coming autumn the fiftieth anniversary of the discovery of anæsthetics. The details of the celebration are not yet fixed, but it will probably take place during the session of the French Surgical Congress in October.

Closure of a Hospital.—The Mount Vernon Hospital was closed the last day of August, owing to lack of funds, and the managers have concluded not to open again unless the city will appropriate an amount sufficient for the needs of the institution.

Tuberculosis and Telephones.—It is said that Vienna physicians have traced cases of tuberculosis and other contagious diseases to the use of public telephones, and the suggestion is made that a sponge with a solution of carbolic acid be kept in every station for a daily cleaning of the apparatus.

The Hospital Sunday Collection in London this year has fallen far below expectations. It is said that Guy's Hospital has taken most of the money charitable persons had to give to hospitals.

Professor Gusserow has been appointed dean of the medical faculty in the University of Berlin for the year 1896-97.

Dr. Jacob Rosenthal died at Chicago, on August 24th, at the age of thirty-three years. He was graduated at the Jefferson Medical College in 1888, and after a period of post-graduate study abroad engaged in the practice of his profession at Chicago, devoting himself especially to gynecology.

Vital Statistics of Philadelphia.—For the week ending August 22d there occurred in the city of Philadelphia 382 deaths, of which 187 were in children under five years of age. The largest number of deaths from a single cause—66—was due to cholera infantum, and the next largest number—39—to sunstroke. There were reported during the week 55 cases of typhoid fever, 23 of diphtheria, and 14 of scarlet fever.

The Estimated Cost of a Medical Education in Berlin is 2,300 marks, about \$575. The fee for matriculation is 18 marks; for examination for the medical faculty, 242 marks; diploma fee, 440 marks; fees for all necessary lectures, etc., 800 to 1,200 marks; cost of printing the dissertation, about 150 marks; and the necessary books and instruments, 500 marks. Then for board, lodging, and clothes, at least 7,600 to 8,000 marks must be added, and much more if one would live in ordinary comfort.

The Ownership of the Prescription.—The *Medical Press*, speaking of a proposal to prohibit the redispensing of prescriptions, on the ground that it would check the sale of poisons and other dangerous drugs, remarks: "We rather think that the purpose is to secure for the general practitioner an additional fee whenever a repetition of medicine is needed. Such a suggestion may, perhaps, be grateful to a certain class of practitioners, but in our opinion it is consistent rather with the commercial morality of America, whence it emanated, than with that of the 'Old Country,' and is en-

tirely beneath that which ought to govern our profession. A patient who pays his money for a prescription seems to us to be quite as much entitled to the unrestricted use of that document as he would be to the use of any other purchased article."

Black Diphtheria in New Jersey.—An epidemic of black diphtheria has been prevailing in Stockton, N. J.

Unethical or Too Popular.—A strong opposition was made this year to the re-election of Mr. Christopher Heath to the presidency of the Royal College of Surgeons, the main objection urged against him being apparently that he had degraded his office by accepting an invitation to give in America a course of lectures to which an honorarium was attached. It surely cannot be regarded as unethical or beneath the dignity of a surgeon in England to receive a fee for strictly professional work, and he could hardly be expected to be so generous as to pay his own travelling expenses besides giving his time in order to deliver a course of lectures to an American audience. Possibly Mr. Heath's opponents thought he ought to confine his remarks to his own countrymen, or possibly they were simply animated by vulgar jealousy.

The Moscow Congress.—The following are the titles of the subjects set for discussion in the surgical section of the International Medical Congress, August 19-26, 1897: 1. "The Treatment of Infected Wounds." 2. "The Non-operative Treatment of Malignant Growths and the Results of Serum-Therapy." 3. "Results of the Operative Treatment of Cerebral Tumors and of Jacksonian Epilepsy." 4. "Surgery of the Lungs, with Special Reference to the Treatment of Tuberculous Cavities and of Pulmonary Gangrene." 5. "Treatment of Cancerous Stricture of the Œsophagus, Pylorus, and Rectum, with the Results Obtained." 6. "Gonorrhœal and Syphilitic Affections of Joints." 7. "The Principles of Construction of Different Forms of Prosthetic Apparatus for Deformities following Diseases of Joints, Paralytic Affections, Congenital Dislocations of the Hip, and after Amputations."

Yellow Fever in Cuba is increasing steadily and is reported to be of a most virulent type. Its victims are found almost exclusively in the Spanish army, the ill-fed and ill-housed youths composing that army succumbing almost with the first touch of the disease. The official report of the Spanish army sanitary corps for the second ten days of July shows that there were in the military hospitals of Cuba at the end of that period 8,838 cases, 5,538 of which were new, and that 346 deaths occurred, 250 being due to yellow fever. Since that date the number of cases is said to have largely increased, but the exact figures cannot be ascertained, as the Spanish authorities are always tardy in publishing their reports. The building of the University of Havana is to be converted into a hospital, as it is now of little use, owing to the lack of students. The epidemic of small-pox in the island is gradually subsiding, through want of fresh material for the disease to feed upon.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 11, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

DR. EUGENE HODENPYL presented a series of specimens illustrative of

The Association of Malignant Disease and Tuberculosis.—For the first specimen he was indebted to Dr. Thacher. It had been removed from a man, fifty-three years of age, who ten months ago had developed a small tumor on the right side of the neck, opposite the thyroid cartilage. One month later the growth had been removed at the German Hospital. It had soon reappeared. When next seen it extended up from behind the angle of the jaw to the median line, was nodular, very hard, and adherent to the skin, jaw, and deep structures. There was some superficial ulceration. One week ago the breathing became very difficult and painful. The urine was normal. The temperature varied from 99.5° to 101.5° F. At the autopsy the upper lobes of the lungs were found to be the seat of a recent tuberculosis, and the tongue contained an epithelioma. On the right side, opposite the thyroid cartilage, was an infiltrating growth, which had ruptured into the œsophagus. Several sections had been examined, but no evidence of tubercles found in the epitheliomatous mass.

The second specimen showed not only the two lesions occurring in the same individual, but the combination of the two diseases in the same lymph nodes. The patient, a man of forty-four years, gave no tuberculous or syphilitic history. He had had a small gland in the neck since childhood, but it had not undergone any appreciable change during all this time. Last March a small ulcer was noticed on the right side of the tongue, which soon healed. During the summer a small painless lump appeared under the jaw. Last November an ulcer appeared on the tongue and soon began to increase rapidly. On admission, in February, he was moderately emaciated and was expectorating profusely. On the right side of the tongue and floor of the mouth was a small growth, which was somewhat ulcerated. There was a lymph node underneath the angle of the jaw. Dr. McBurney removed the tongue by Kocher's operation, together with the lymph node. In the lymph node (shown under the microscope) was a combination of the lesions of tuberculosis and epithelioma. He had stained a number of sections for tubercle bacilli, but with negative result. The miliary tubercles were slightly cheesy in their centres, and contained a considerable number of giant cells.

The speaker said that George Clement, in Virchow's *Archiv* for 1895, had presented an excellent *résumé* of the literature of the subject. The combination of tuberculosis and epithelioma or carcinoma in the same organ had been described by a number of observers, but in all less than fifty typical cases of this kind were on record. The combination of tuberculosis and epithelioma in the same individual was much more frequent. Lubosch's conclusions, from his study of this subject, are: (1) That carcinoma may be engrafted on an old tuberculosis, and that half of all the cases reported belong to this class; (2) that an old case of tuberculosis may become carcinomatous, and the carcinomatous cachexia facilitate a fresh tuberculous eruption—a rare occurrence; (3) that a carcinomatous person may become tuberculous, although only three instances of this kind were found on record; (4) that a chronic, progressive tuberculosis may act as a

predisposing cause to carcinoma, in the same manner that a local traumatism predisposes to malignant disease. Dr. Hodenpyl said that in the case reported it seemed to him that the two lesions were probably nearly simultaneous in their occurrence. There was no tuberculosis found in the primary tumor.

DR. GEORGE P. BIGGS said that this specimen was interesting to him in connection with the case of giant cells which he had presented some time ago. The two conditions might easily be confounded. The rarity of the association of malignant disease and tuberculosis seemed to him to be partly explained by the different periods of life in which these diseases usually appeared. One susceptible to tuberculosis generally succumbed to this disease before arriving at the age at which carcinoma or epithelioma or dinarily developed.

DR. J. S. THACHER recalled a case seen clinically about one year ago, occurring in a nurse, about forty-five years of age. This woman had presented only certain vague abdominal symptoms, and several physicians had failed to make a positive diagnosis. At the autopsy there was some difference of opinion as to whether the case was one of tuberculosis or carcinoma. The peritoneum seemed to show typical miliary tubercles, but in the pancreas were nodules looking more like carcinoma. Dr. Coleman found, on making sections, that both conditions were present, the tuberculosis involving principally the peritoneum.

THE PRESIDENT said he thought he had discovered in the specimen under the microscope areas of cheesy degeneration in the newly-formed epitheliomatous tissue, suggesting that at least in those places the tuberculosis was of more recent development than the epithelioma. He could not see any reason why tuberculosis and carcinoma should not be associated; it was a pure assumption to suppose that they were in any way antagonistic. He recalled a case of extensive secondary carcinoma and diffuse pulmonary phthisis in the same lung. He thought such cases were not so very rare; probably they had been overlooked or not thought worth reporting.

DR. HODENPYL then presented microscopical specimens of

Multiple Miliary Aneurisms of the Left Anterior Cerebral Artery.—These had been taken from a rather elderly lady, who, while apparently in fair health, had suddenly fallen forward from her chair and become unconscious. She died soon after admission to the hospital. At the autopsy the thoracic and abdominal organs were found comparatively normal. There was no atheroma of the larger vessels of the thorax and abdomen. There was, however, a well-marked atheroma of all the vessels at the base of the brain, and the left anterior cerebral artery presented what looked to be multiple miliary aneurism. The vessel was studded with from ten to fifteen small nodules, varying in size from that of a pin's head to three or four times that size. There was a considerable extravasation of blood at the base of the brain; evidently the hemorrhage had occurred from rupture of one of these small nodules. Microscopical examination showed very extensive disease of the vessels. In at least one place rupture had taken place into a blood-vessel, so that it was really an aneurism; in the other places the more accurate designation would be "atheromatous cysts."

Acute Exudative Meningitis.—Dr. Hodenpyl showed some microscopical specimens from a case of this kind, in which there had been scarcely any gross lesions. He thought the diagnosis could not have been made except by the aid of the microscope. The patient, a colored man, twenty-three years of age, was admitted to the hospital on January 19, 1896. He was very intemperate in his habits, and had had syphilis two years before. About the middle of last November he had begun to suffer from dizziness and

headache, but these had temporarily improved under antisyphilitic treatment. The headache had then returned and become more severe. On admission he was well nourished, the breath was foul, there was considerable prostration, the urine was normal: the temperature was 100° F., pulse 66, and respirations 22. The physical examination was negative. On the day after admission he was found to be stupid and he passed no urine. Fourteen ounces of urine were drawn by catheter. On January 22d, two days later, there were convulsions and coma. The next day he could hardly be aroused from his stupor. On January 25th there were convulsions again. On January 28th he died. While in the hospital the temperature had been between 99° and 100.8° F., the pulse between 64 and 128, and the respirations between 16 and 24. At the autopsy the pia mater was congested and somewhat dry, and although its lustre was slightly diminished its appearance was not at all characteristic. A very small amount of clotted blood was found at the base of the brain, and a little slightly blood-tinged fluid in the lateral ventricles. All over the convexity of the brain on either side the microscope showed a moderate exudation in the meshes of the pia, and little on the surface. The exudate consisted of serum, fibrin, and leucocytes, with a few blood cells and cells from the pia itself.

The speaker said that three kinds of meningitis normally showed no gross lesions, viz.: (1) Acute cellular meningitis, which was comparatively rare; (2) tuberculous meningitis, either with or without exudative meningitis; and (3) acute exudative meningitis. It seemed to him quite remarkable that such a small lesion should prove fatal, as it undoubtedly did.

DR. GEORGE P. BIGGS referred to a similar case, that of a girl who had frequently been in the Hudson Street Hospital for hysteria. One day, just as she was about to be discharged from the hospital, she fell dead. The autopsy showed no very clear cause of death, except that the pia mater seemed to be a little dry and dull. Microscopical examination was made of the medulla, cerebellum, and cerebrum, and in all these parts an exudate was found. This consisted of an extremely thin layer, but containing many cells. The rapidity with which death might occur in these cases was interesting. He remembered a case in which a boy had died within twenty-four hours of the onset of the first symptoms. Microscopical examination in this case disclosed the cause of death.

The next specimen, presented by DR. HODENPYL, was from a case of

Primary Carcinoma of the Liver and Head of the Pancreas.—It had been taken from a woman, twenty-seven years of age, who had been comparatively well up to one year before her death. At that time she had begun to have some jaundice and offensive diarrhoea, with abdominal pain. For three weeks prior to admission she had had pretty constant pain to the right of the epigastrium. On admission she was moderately emaciated, intensely jaundiced, and suffering considerable pain in the epigastrium. The abdomen was moderately distended with fluid. The area of liver dulness was very decidedly increased, and also the splenic dulness. There was an irregular fever, the temperature sometimes rising as high as 103° F. About two days before death an exploratory operation was performed. An enormously distended gall bladder was found, and also a new growth in the region of the pancreas. An anastomosis was made between the gall bladder and the intestine by means of a Murphy button. Death occurred from peritonitis and shock. At the autopsy the abdomen was found to contain about two quarts of bloody fluid, and the intestines were distended with tarry blood. The intestinal suture was tested and found to be complete. The gall blad-

der contained two ounces of dark bile. The stomach was dilated and the mucous membrane bile-stained. The left half of the pancreas was soft. The organ was greatly enlarged, and behind and firmly adherent to the duodenum and under surface of the liver was a new growth. In the duodenum were two circular openings with rounded edges, communicating directly with the necrotic new growth. A probe passed only a short distance into the common duct. The gall bladder at the cystic duct opened by a solution of continuity directly into the cancerous mass. The liver was enlarged and intensely bile-stained. The gall ducts were greatly congested. The kidneys showed acute degeneration.

THE PRESIDENT remarked that some time ago he had presented similar cases to the society. In two of them the patient had died so early that all that was found was a nodule restricted to the head of the pancreas. The particular interest in the case was the demonstration of the fact that carcinoma did occasionally begin in the head of the pancreas.

Carcinoma of the Liver and Stomach.—The next specimen presented by DR. HODENPYL was from a man, fifty-two years of age, admitted to the hospital in November. Three months before, he had been successfully operated upon for hydrocele. At the time of his last admission the abdomen was distended, but no fluid was withdrawn from it. Physical examination showed the liver considerably enlarged. Emaciation and enlargement of the liver were the only evidences of disease, and these were steadily progressive up to the time of his death. At the autopsy there were three quarts of bloody fluid in the abdominal cavity. The liver weighed twelve pounds, and was almost completely replaced by carcinomatous new growth. At the pylorus was a carcinomatous mass, just beginning to ulcerate. There was also a small carcinomatous mass at the head of the pancreas.

Primary Carcinoma of the Stomach with Perforation through the Duodenum into the Lung.—The patient from whom Dr. Hodenpyl took these specimens was a man, fifty-one years of age, who gave a history of vomiting after meals for a year before death. Shortly before the last he developed some fever and cough, with very fetid expectoration. In the lesser curvature of the stomach the autopsy revealed a large carcinomatous mass and an opening admitting two fingers. This opening passed into the lower lobe of the lung, in which was an abscess about the size of an orange. The next specimen was one of

Carcinoma of the Pylorus, removed from a man, fifty-six years of age, who had had vomiting and slight pain in the stomach for two years previously. He had emaciated gradually, but there had been no vomiting of blood. Microscopical examination showed the carcinoma to be of the colloid variety. The next specimen was from a case of

Carcinoma of the Stomach without Symptoms.—It was removed from an old man who had been found in the street, bleeding from the mouth. He died at the hospital before any history could be obtained. At the autopsy the man looked to be strong and well nourished. The stomach and intestine were filled with large blood clot, the stomach contained a large coagulum, and at the cardiac orifice was an encircling and constricting carcinomatous mass with a number of blood-vessels traversing this ulcerated growth. The next specimen was one of

Carcinoma of the Stomach with Marked Constriction of the Pylorus.—This was not accompanied by a clinical history. The last specimen by Dr. Hodenpyl was one of

Syphilitic Perforation of the Large Intestine, occurring in a man, sixty-one years of age. He had had a well-marked attack of syphilis, for which he had

been treated. There was a syphilitic necrosis of the sternum. He came into the hospital complaining of obstinate constipation. Enemata and powerful purgatives were given, without causing a movement of the bowel. At the autopsy several syphilitic gummata were found in the spleen, and in the abdominal cavity was a beginning peritonitis. There was also a large quantity of faecal matter in the abdominal cavity.

A Peyer's Patch in a Meckel's Diverticulum.—DR. THOMAS S. SOUTHWORTH presented the intestine of a child of seven months, who had died of chronic catarrhal enterocolitis. The solitary follicles were enlarged and Peyer's patches swollen. About one foot above the ileo-caecal valve was found a small Meckel's diverticulum, in which was a Peyer's patch.

Ileo-Colic Intussusception.—The second specimen was from a child of two months, evidently syphilitic. There had been high fever and some pulmonary consolidation just before death. At the autopsy the posterior portions of the two lower lobes showed patches of broncho-pneumonia. The spleen was enlarged, apparently from syphilis, and the organ weighed thirty grams. In the lower portion of the ileum were six intussusceptions, and one of them of the typical ileocolic variety. These intussusceptions, the speaker said, occurring just prior to death, are usually in the jejunum.

The society then went into executive session.

Stated Meeting, March 25, 1896.

Resume of the Uses of Formalin.—DR. GEORGE C. FREEBORN read a paper with this title.

DR. HENRY POWER said that in his experience formalin had appeared to be very irregular in its action. He had noticed this especially in studying the minute anatomy of the cells.

THE PRESIDENT asked if it had been found that the freshness of the tissues was an essential point in the successful use of this agent.

DR. FREEBORN said that when formalin had been first brought into use he had directed the specimens to be placed in a two-per-cent. solution in the operating-room, and this plan had yielded excellent results. Subsequently he had found the specimens very poorly preserved, and he had then increased the strength of the solution to five per cent., with rather better results for a while, but again there had been trouble. Finally he had adopted the plan of substituting a two-per-cent. solution of formalin for the water ordinarily employed in Müller's fluid. Since then he had used this "formalin-Müller's fluid" and there had been no trouble.

THE PRESIDENT said that recently in preparing a specimen for the museum his attention had been directed to this matter. A heart had been mislaid, and had become quite foul before he had seen it. It was placed in a two-per-cent. solution of formalin, and notwithstanding the very bad condition of the specimen when placed in this fluid it had been restored to nearly as good condition as if it had been immersed in alcohol or in formalin when quite fresh. He would like to ask whether Dr. Freeborn had noticed any effect on the diffuseness of the staining with the hæmatoxylin as a result of delay in putting the tissues in the formalin.

DR. FREEBORN replied that he had noticed this diffuse staining in the amnion of some pigs when there had been a delay of three or four hours before immersion in the formalin solution. Kohn had experimented on a putrefying solution of peas, using various strengths of formalin, and he had found that anything above a five-per-cent. solution would sterilize and deodorize this "pea soup." Many other similar investigations had been made with like results.

DR. F. M. JEFFRIES referred to two mishaps with formalin in preserving the intestine. After the specimens had been placed in a two-per-cent. solution of formalin for about three days they had turned black. He had been at a loss to account for this. Possibly it might have been due to some medication that had been used, but it had ruined the specimens.

DR. THOMAS S. SOUTHWORTH said that he had placed a number of children's lungs in a two-per-cent. formalin solution for a considerable time, and had obtained a blackish-gray discoloration, which had not been entirely removed by alcohol. It was probably due to the length of time the specimen had been in formalin before being transferred.

DR. FREEBORN said that a foetal pig that had been put in a ten-per-cent. solution of formalin about eighteen months ago still retained its white color beautifully. As formalin is an oxidizing agent, it was quite possible that something in the intestine had formed a dark chemical compound with the formalin.

DR. POWER said that he had preserved fourteen specimens of intestine in formalin without observing this discoloration. They had not remained for any length of time.

DR. EDWARD LEAMING said that formalin was used frequently in photography for the hardening of gelatin plates. The action of formic acid should be to reduce the silver salts, and he had found that this had occurred in unexposed plates. A similar reduction might occur with salts of other metals.

DR. FREEBORN said that sometimes there was an overoxidation of the methylic alcohol in the manufacture of formalin, by which formic acid was produced. He had also found that this oxidation would sometimes continue in open vessels, resulting in the formation of a considerable quantity of formic acid.

Improved Stage for Use in Photomicrography.—DR. EDWARD LEAMING exhibited a new form of apparatus intended for use with the microscope in photomicrography. It was found in certain cases that in attempting to photograph a slightly uneven specimen, or a nerve cell with a long process, it was impossible to get it all in the same plane with the slide held in the usual way. To surmount this obstacle, the apparatus exhibited had been devised by the assistant to Mr. Kraft, of this city. It consisted of a light framework and a light stage on which the specimen was clamped. By means of an ingenious screw adjustment the slide could be tipped in various directions and across the axis of the lens.

Reproduction of Photomicrographs.—DR. LEAMING made some remarks on this subject, illustrating them with some beautiful examples of such work in colors. He said that he had attempted to utilize in reproducing photomicrographs the three-color photography by the gelatin process. The image was first focussed through a violet screen, and then negatives were taken successively through red, violet, and green screens. These are the complementary colors to the three colors in which the photograph is finally printed. The negative taken through the red screen is printed in blue, that through the green screen is printed in red, and that through the violet screen is printed in yellow. The color screens are made of glass and tough collodion properly colored. From these negatives three bichromate gelatin printing-plates are obtained and the printing is done by superposition. Unfortunately, the manner of printing alters the results somewhat, and, although this is of no importance in ordinary artistic work, it is a serious drawback to the use of this process for purely scientific purposes.

DR. FREEBORN exhibited under the microscope the original slides from which the colored photographs had been made.

DR. POWER said that he had taken a great deal of interest in this subject in connection with general photography. The lack of registration is a difficulty with the printer, but probably there would be difficulty in the registration even aside from the fault of the printer, owing to the imperfections in our lenses and the slight differences in the size of the images for the different colors. He thought it possible that changing the camera length might obviate this. A moderate amount of change in the length of the camera would produce only a very small change in the image.

DR. LEAMING said that he thought Dr. Power was in error on this point, for focussing, to be of service, must be done chiefly through the objective and not by changing the length of the camera. It was more difficult to focus through a violet screen, but if this were done the images would be more nearly perfect.

Instrument for Cutting Off the Spinal Cord.—

DR. PEARCE BAILEY said that in order to avoid the mutilation of the spinal cord which occurred when it was taken out in the usual way, he had devised an instrument, consisting of a small, slightly curved blade at right angles to the stem. This knife should be inserted some distance into the spinal canal and the cord cut off at right angles. This also gave a much better specimen for making sections.

DR. JAMES EWING thought the instrument should prove very useful. In removing the cord anteriorly it was usually very difficult to extract the last two or three inches, but with this new instrument this could be done from above.

Preservation of Specimens of the Intestines.—

DR. HENRY POWER said that about one year ago he had presented to this society a preliminary report on the preservation of the intestine. He had continued this line of experimentation since that time, using children as the subjects. At first, the best method had seemed to be the injection through a cannula of a two-per-cent. solution of formalin very slowly into the rectum. For the past year most of his experiments had been done with only eight or ten inches of pressure, and with a two-per-cent. solution of formalin, both peritoneum and bowel being injected in the majority of cases. He had learned that one of the most important points in the preservation of the intestine was not to handle it. The formalin appeared to penetrate rapidly from the peritoneum to the mucous membrane: hence it was better to inject into the peritoneum. He had selected formalin because of its gaseous and penetrating nature. From three to five specimens had been taken from the various parts of the bowel, and they had been uniformly preserved, much better than in the usual way. In these experiments he had been assisted materially by Dr. Southworth. In one case the injection had been made shortly after death, and the autopsy performed forty-three hours afterward. In another case the injection had been made twenty-four hours after death, and the autopsy performed shortly after this, the intestine being found in a state of excellent preservation. He had found that the anatomical relations of the cells were excellently preserved, although the minute anatomy of the cells was not so good.

DR. EWING said that in looking over these specimens he had been impressed with the marvellous preservation of the endothelial cells. The nuclei, the cell bodies, and the outlines between the cells could be easily distinguished. He had never seen this with any other method of preparation.

DR. SOUTHWORTH said that Holt, in his article in Keating's Encyclopedia, stated that he rarely found the epithelium present if the autopsy were made more than six hours after death, and he expressed the belief that the desquamative catarrh was the most frequent form of acute intestinal disorder in children. This,

the speaker said, he was inclined to doubt, for even when their autopsies had been made twenty-four hours after death the epithelium had been preserved.

Photomicrographs by the Carbon Process.—DR. POWER then presented several photomicrographs by the carbon process. He said that the great advantage of the carbon process was that the prints were entirely permanent. As the pigment was either a finely ground earth or finely pulverized carbon, and the background apparently some form of lime suspended in gelatin, even the yellowing of the paper was avoided. He presented photographs of tissues done with an amplification of from ten to a thousand diameters, and of bacteria with an amplification of from seven hundred and fifty to one thousand diameters. He used monochromatic light with "critical illumination" from the sun, and the plate was backed with some substance which would not spread through the film, so that there would be no spreading of the image from the whites into the blacks.

A New Form of Degeneration of the Ovary.—

DR. MARY A. DIXON-JONES presented four microscopical specimens illustrating what she considered to be a new form of degeneration of the ovary, by which most of the organ was changed to myxomatous tissue. Out of eighty diseased ovaries examined she had found four specimens showing this degeneration. This condition was associated clinically with marked deterioration of the general health.

The society then went into executive session.

Stated Meeting, April 22, 1896.

Tumor of the Cerebellum.—DR. FREDERICK PETERSON presented a tumor of the middle lobe of the cerebellum, removed from a boy of twelve years, who had been sent to him for examination in July, 1895. About Christmas of 1894, up to which time the patient had been perfectly well, he had an attack of grippe with meningeal symptoms. After recovery from this he suffered from periodical headaches, which grew worse. These headaches were frontal, occurred once a week, and lasted a few hours. Sometimes he was delirious during these attacks. Six months previous to coming under the observation of Dr. Peterson, he was said to have had optic neuritis. The examination revealed the following: Optic atrophy with feeble perception of light, knee-jerks absent, no nystagmus, no ocular palsies, no paralysis nor alteration of sensibility; pulse and respiration normal. He had attacks of headache with vomiting weekly. A very peculiar symptom was constant choreiform movements of the head, mouth and face muscles, and all four extremities, precisely like an ordinary chorea. There was a staggering gait. The diagnosis of a glioma or gliosarcoma of the middle lobe of the cerebellum was made, the symptoms being typical. The boy, while on a visit at Syracuse some time ago, fell down stairs, fractured his skull, and died. Dr. Van Duyn, who made the autopsy, had kindly sent him the brain. On microscopic examination by Dr. Bailey the tumor proved to be a glioma, and its situation in the vermis was verified. The tumor was encapsulated, was five centimetres broad and 2.5 centimetres deep, and lay directly in the vermis, encroaching equally on each side into the lateral lobe of the cerebellum. The fourth ventricle was widely dilated, and the whole bulk of the pons seemed to have been subjected to considerable compression. Dr. Peterson said he had seen many cases of tumor of the cerebellum, but never before one with the choreiform movements which distinguished this case.

Primary Pernicious Anæmia.—DR. JAMES EWING, in discussing this subject, reported the following illus-

trative case: The patient, a man of forty-five years, of American parentage, had been admitted on April 9, 1896, to the Roosevelt Hospital. His family history was negative. There was a moderate alcoholic habit, and some years before he had had symptoms of secondary syphilis. For five weeks prior to his admission it was stated that he had been very pale, and had suffered considerably from dyspnoea on exertion. There had been no disturbance of vision, no headache or dizziness, but for four weeks there had been œdema of the extremities, and he had lost a good deal of strength. The urine was of dark color and scanty. On admission he was markedly pale, but not jaundiced; the pulse was regular and small, the arteries were apparently normal, there was considerable œdema of the feet and legs. The splenic area was slightly increased. He was given arsenic and iron, but without benefit. On April 10th the hæmoglobin was twenty-five per cent., and the blood count showed one million one hundred and twenty-eight thousand red blood cells. A dried preparation showed that the condition was one of primary progressive pernicious anæmia. The size and form of the blood cells were very characteristic. There were very fine microcytes, very large megalocytes, and giantoblasts in abundance, and great variations in the intensity of the hæmoglobin stain. There was a considerable increase in the white blood cells, chiefly in the polynuclear leucocytes, and some large myelocytes were found. On April 11th he was given five minims of Magendie's solution of morphine to produce sleep. After this dose he went into profound collapse, and was with difficulty resuscitated. On April 13th he suddenly began to have difficulty in breathing, and he died four hours later, with symptoms of asphyxia.

The autopsy was made two hours after death. The lungs were emphysematous and extremely anæmic, except for some small areas of consolidation. The bronchial glands were slightly enlarged. The pericardial sac contained a few ounces of reddish fluid. The right heart was distended by a peculiar soft blood clot. No other clots were found elsewhere, and it was evident that the coagulability of the blood was greatly diminished. The total quantity of blood also appeared to be diminished. The heart was nearly normal. The liver was enlarged and very firm. The outlines of the lobules were very distinct, and the peculiar rust color of the organ was very striking. The spleen was markedly enlarged, weighing thirteen ounces. The kidneys were somewhat smaller than usual. The surface was granular, the cortex was thin, the markings were indistinct, and the whole organ was somewhat congested. In the intestine there was an abnormal adhesion binding the transverse duodenum down to the lumbar vertebrae, and producing a slight narrowing of the lumen. There was evidence of catarrhal enteritis, but there were no parasites present. The bowel contents consisted almost entirely of mucus, giving a remarkably strong odor of hydrogen sulphide. The sternum, ribs, vertebrae, clavicle, humerus, and hyoid bone had been examined, and in all these situations there was very extensive increase in the marrow cavities, and these cavities were filled with red marrow.

Microscopical examination showed in the spleen no increase of connective tissue, a marked diminution of cellular elements, both of the Malpighian bodies and of the spleen pulp. In many of the Malpighian bodies the small round cells were entirely wanting. A slight reaction for iron, hæmosiderin, was developed by potassium ferrocyanide and acidified glycerin, but it was much less marked than in the liver. There was no granular pigment observed as a result of the extensive destruction of the red blood cells in the spleen. The thyroid showed a very marked general thickening

of the trabeculae, with partial atrophy of many alveoli. In the liver there was slight general increase of fibrous tissue between the lobules and between the liver cells. The liver cells showed marked fatty degeneration. The nuclei and numbers of the liver cells were distinctly increased in number, and some of these new cells and nuclei were of very large size. Throughout the liver there was an abundant deposit of yellowish pigment granules, giving a very distinct reaction for iron. In the stomach there was a moderate grade of chronic catarrhal inflammation, with increase of connective tissue and atrophy or dilatation of glands. In the lower dorsal and lumbar regions in the spinal cord, the only parts examined, there was slight sclerosis of the columns of Goll, but without pronounced atrophy of fibres in this region. Nissl's stain showed ganglion cells to present in moderate degree an absence of chromophilic granules about the nuclei, in many cells, while other cells showed extensive deposits of greenish pigment commonly seen after middle life. The red marrow was found in all the bones examined—the ribs, sternum, vertebrae, clavicle, humerus, and hyoid. In all of these bones the cancellous spaces were very much widened and filled with light red semifluid marrow. The shafts or outer plates of these bones were distinctly thinner than normal. The head of the humerus could be easily crushed in by pressing on the cut surface of the cancellous tissue. No fatty marrow was seen in any of these bones. Cover-glass preparations were made from the various organs concerned in blood formation and stained in Ehrlich's triacid mixture. So far as could be judged by this method, while the red marrow in all the bones contained a large number of megaloblasts, the total number of nucleated red cells was considerably less than is to be found in normal adult red marrow. In the preparation from the ribs, the nucleated red cells did not compose more than one-fiftieth part of the cells present. All the red cells, both nucleated and non-nucleated, seemed to number about one-eighth of all the cells in the marrow of the ribs and other bones. While, therefore, the locality of the formation was very much widened, it did not seem that the number of the red cells in active proliferation was correspondingly increased. The majority of the new cells in the red marrow consisted of small and large mononuclear cells, myelocytes, polynuclear neutrophile leucocytes, and eosinophile leucocytes. While the manufacture of red cells was here very widely distributed, it seemed that the total productive capacity was probably diminished rather than increased.

Dr. Ewing here illustrated his remarks by exhibiting charts and slides. The first showed the blood from a case of pernicious anæmia, with the characteristic megalocytes and the small basophilic granules in the megaloblasts. A chart of the blood from a case of chlorosis was also exhibited. This showed that the blood cells were moderately diminished in number, and there was a general diminution in the hæmoglobin. In this case one did not see in any quantity the large megalocytes of pernicious anæmia. A common form of degeneration, the speaker said, was the extrusion from the body of the red cell of a mass of protoplasm, which stains with methyl blue and which gives all the characteristics of the blood plate. A chart showing the characteristics of the blood of secondary pernicious anæmia was also shown, and the relations of this condition to primary pernicious anæmia were discussed.

The examination of such a typical example of pernicious anæmia, in which all the essential features of the disease were so strikingly developed, naturally suggested, Dr. Ewing said, some considerations regarding the etiology and pathogenesis of the disease. It was now generally admitted that pernicious anæmia

is primarily a condition of excessive hæmatolysis rather than one of defective hæmatogenesis. While very acute cases of pernicious anæmia had been recorded, in which the characteristic changes in the bone marrow, leading to defective hæmatogenesis, were absent, the disease seemed not to exist without excessive hæmatolysis. He had recently had an opportunity, through the kindness of Dr. Northrup, of examining an acute case, lasting only four weeks. In this patient the red cells numbered less than five hundred thousand per cubic centimetre. There was an almost entire absence of nucleated red cells of all varieties and of abnormally large red cells, although degenerative changes in these red cells were extensive. While no autopsy was made, the observations of Ehrlich had shown that such cases were unattended by the usual changes in the bone marrow. As evidence of the excessive destruction of red blood cells in pernicious anæmia, one might refer to: (1) the abundance of degenerative changes in the red cells; (2) the coloration of the plasma as seen in dry preparations; (3) the deposit of large quantities of iron in the liver and spleen; (4) the appearance of excessive and pathological blood pigments and of an excessive amount of iron in the urine; and (5) in the acute cases the very rapid diminution in the number of red cells present in the blood.

But these facts were not conclusive proofs that excessive hæmatolysis was the sole factor in the production of the disease. Degenerative changes in the red cells are abundant in chlorosis and in secondary anæmia, when the number of red cells is not markedly reduced and when iron is not always present in excessive amount in the liver or in the urine. Neither is the presence of an excess of iron in the liver a positive indication that pernicious anæmia has existed. In a series of examinations of forty-four livers, taken as the cases came to autopsy, Russell found in seven quite as much iron as Hunter found in the liver of pernicious anæmia. These were cases of marked secondary anæmia from cancer, tuberculosis, and other diseases, and the patients had not suffered from pernicious anæmia. In those cases of pernicious anæmia which follow pregnancy, it was difficult to see what could be the toxic agent which could alone initiate and continue a fatal destruction of red cells. Even more difficult was it to explain those cases which follow large hemorrhages by the assumption that there is present in the blood a toxic agent which continues the destruction of red cells. An examination of the clinical aspect of the disease seemed to show that, according to their etiology, there were cases of pernicious anæmia which were very probably caused by a toxic agent circulating in the blood and destroying red cells, and that there were other cases which could be most reasonably referred principally to defective hæmatogenesis. In the first class might be placed those examples of the disease which were associated with the presence of intestinal parasites or blood parasites, such as the *cercomonas globus* or the malarial organism; also the cases following infectious diseases. Of the idiopathic forms, while the very acute cases, unattended by marked changes in the bone marrow, were most naturally referred to excessive hæmatolysis, it was difficult to see how a toxic agent destroying red blood cells could, in a few weeks, have produced changes in the bone marrow of such enormous extent as were found in the case just reported. It was much more probable that an abnormal process of cellular proliferation, leading to defective hæmatogenesis, was the chief factor in the production of the blood changes in this case. It would appear, therefore, that both excessive hæmatolysis and defective hæmatogenesis were essential features of the disease process in pernicious anæmia, and that sometimes one and sometimes the

other was the more prominent. The speaker said that a large number of studies had been undertaken with a view of determining the nature of the toxic material which destroys the red cells in pernicious anæmia. The studies of Hunter in this direction were important. In an article in the *British Medical Journal*, February 8, 1896, he reported some recent experiments, and supported his previous conclusions that pernicious anæmia is a specific form of blood destruction, occurring chiefly in the portal circulation and caused by the absorption of the products of intestinal bacteria. Cadaverin and putrescin he regarded as the probable agents concerned. Jurgenson had reported a case of pernicious anæmia cured by the removal from the intestine of enormous numbers of the bacterium *termo*, and Liebman had produced a condition of chronic blood poisoning resembling pernicious anæmia by the intravenous injection of hæmoglobin, of glycerin, and of pyrogallie acid. He believed the disease to be due to hæmoglobinæmia. The followers of the Dorpat school believe that the poisonous agent in the blood of pernicious anæmia comes from the destruction of both red and white blood cells. The nervous origin of pernicious anæmia had received some little support. Some of the cases reported, like the present one, showed changes in the central nervous system, but in no instance did these changes appear to be of more than secondary importance. The theory most widely accepted was that the disease represented a rapid form of blood destruction, associated with a reversion of the blood-forming function to the embryonal type: in other words, it represented a tumor formation in a fluid tissue. This analogy to a tumor formation, however, appeared to be more applicable to leukæmia than to pernicious anæmia. A comparison of the blood of foetal vertebrates with that seen in cases of pernicious anæmia certainly did show many points of resemblance, but the likeness did not seem to him to be especially striking.

DR. THOMAS S. SOUTHWORTH said that in examining cases of pernicious anæmia he had met with difficulty in diagnosis owing to the intermediary class of cases. Many cases were diagnosticated clinically as acute primary pernicious anæmias. He had come to rely upon two things, viz.: the existence of megalocytes—the large non-nucleated red cells—and the presence of the megaloblasts—the oval, large, nucleated red cells. Unless these were present in considerable numbers, however, the diagnosis could not be positively made.

Dr. Southworth then exhibited microscope slides illustrating these points, and presented microscopical specimens from a case of

Rachitic Anæmia.—He said that in January of the present year a baby of eighteen months, with marked evidence of rachitis, had been admitted to the Babies' Hospital. The spleen had extended to the left anterior superior spine, and measured three by two inches below the ribs. The liver had been enlarged, coming down one and one-half inches below the ribs. There had been also some enlargement of the superficial glands. The number of red cells had been five million one hundred and forty-four thousand to the cubic millimetre, the ratio of the white to the red cells being 1 to 168. The most interesting point in this case was the extremely large number of megaloblasts.

Dr. Ewing asked Dr. Southworth as to the relative frequency of the severe forms of pernicious anæmia in connection with rachitis. He said that while he had found a great variety of severe forms of anæmia in connection with rickets, he had not observed progressive pernicious anæmia.

Dr. Southworth said that he had seen many cases of profound anæmia, and the condition had yielded to the usual antirachitic remedies and tonics. In the

case just reported the anæmia was not particularly marked, as there were over five million red cells.

Pernicious Anæmia.—DR. CHARLES FISCHER also presented a microscopical specimen from a case of pernicious anæmia. There was no clinical history. The patient had been in the hospital only three weeks. At the autopsy no other lesions had been found. The specimen showed all the varieties of degeneration that had been described by Dr. Ewing.

The society then went into executive session.

Clinical Department.

A CASE OF SUPPLEMENTARY AMNIOTIC SAC WITH FIBROID TUMOR OF THE UTERUS.

BY DANIEL S. ROBINSON, M.D.,

NEW HAVEN, CONN.

IN the early evening of December 7, 1895, I was hurriedly called to attend Mrs. L—, aged forty-four years, in labor with her third child. On arriving at her home I found her suffering from strong, regular pains, having been in labor since 11 P.M. of the previous day. On examination I found the tense membranes protruding nearly two inches beyond the vulvar orifice, and, as during the interval a normal vertex presentation was made out, at the next pain I ruptured them. The rupture was followed by a profuse discharge of the liquor amnii, but on making an examination at the next pain I was surprised to find that, while the head was low and apparently completely filled the parturient canal, the "bag of waters" still seemed intact.

As all the circumstances of the case seemed to point strongly to some anomaly of the placenta or membranes, I ruptured this second sac and a very few pains sufficed to deliver the patient of a seven-pound girl. More difficulty was encountered, however, in the delivery of the afterbirth. Attempting to deliver by Credé's method, only to fail, I inserted two fingers into the vagina, and found that while the placenta and a portion of the membranes were lying free in the vaginal canal, another portion of the membranes was still *in utero*.

Following this up, I found that it seemed to lead to the left and to be attached in some way to the uterine wall. Gentle manipulation after some few minutes caused detachment and gradually the entire mass was drawn into the vagina and delivered. The uterus did not retract as it should, there being a distinct tumor of the left side about as large as an orange. The patient denied the existence of any tumor, but said "that lump" was always there and gave a history of menorrhagia, which made the probable diagnosis very simple. An examination of the afterbirth showed, about three inches from the placental insertion of the funis, a large sac formed by development of the outer (amniotic) sheath of the cord, and this, having prolapsed in front of the descending head, had given the impression of the membranes being still intact after rupture of the first sac. The capacity of this supplemental sac was about two litres. Whether or not there was any connection between this sac and the fibroid probably existent I don't know, but it is my belief that in some way it was an attempt of nature to save the fœtus from injury during development.

A point in the case of interest to the maternal impressionist is the fact that the second and third digits on each hand are united, caused, the mother believes, by frequent visits during her pregnancy to a friend whose infant child has the same deformity.

DYSTOCIA, DUE TO DISPARITY BETWEEN THE SIZE OF THE HEAD OF THE FŒTUS AND THE CIRCUMFERENCE OF ITS SHOULDERS.¹

BY A. ERNEST GALLANT, M.D.,

FORMERLY INTERNE, SLOAN MATERNITY HOSPITAL, ETC.

THE failure of recent text-books or works on the complications of the above-named condition to mention it as a cause of difficult labor, has determined the writer to place this case on record.

The dystocia and the death of the child can be accounted for as follows: Circumference of the shoulders, 44 centimetres ($17\frac{1}{4}$ inches); occipito-frontal circumference, 33.5 centimetres ($13\frac{1}{8}$ inches—or a difference of 10.5 centimetres ($4\frac{1}{8}$ inches); and secondly, the unusually fat condition of the mother, who weighed two hundred and twenty pounds, the pelvis being so filled with adipose tissue as to seriously interfere with the distention of the vagina. This, with the disproportion between the head and shoulders, compressed the body to such a degree as to stop the umbilical circulation and resulted in the death of the child while in the vagina.

The mother first came under the writer's care at the Roosevelt Hospital, Out-Patient Department, in March, 1894. Native of Ireland, twenty-eight years of age, housewife, married two and a half years. She had borne one child one and a half years ago, and had had a miscarriage in July, 1893. She menstruated regularly every four weeks, for two days. There was pain one day before and during the first day, with some leucorrhœa. She complained of a dragging pain in the lumbar region. The perineum was lacerated nearly to the sphincter ani and the cervix was lacerated bilaterally. The uterus was forward, three and a half inches deep, roomy, and tender on pressure. Diagnosis: Fungous endometritis.

April 14th, dilatation of the cervix, curettage, irrigation with tincture-of-iodine solution (sherry color), resulting in a firm contraction of the uterus. Internal hemorrhoids removed by scissors and the edges brought together with catgut sutures, after the method described in Mathew's *Medical Quarterly*, vol. i., page 518, 1894.

May 2d the patient had an attack of appendicitis and the next day the writer removed the appendix, six inches long, through a five-inch skin incision, made necessary by the fact that the abdomen was covered by fat four inches deep. The appendix was bound down by strong fibrous bands to the colon and lateral abdominal wall. In spite of the thickness of the abdominal wall, the wound was closed by a single line of silkworm-gut sutures passed through all the layers.

November 5th the vulva, cervix, and vagina were of a bluish hue and congested. The last menstruation, July 5th and 6th, was scanty. Pregnancy was normal. The abdominal cicatrix did not stretch.

Labor pains began in the early morning of April 16, 1895, and by 9 P.M. the cervix was drawn up and was very soft; the membranes were bulging, and, owing to their density, were punctured. A small quantity of liquor amnii escaped. The head was in R. O. P., movable above the brim. Pains recurred at intervals of from five to fifteen minutes, but at no time were they strong. The forehead showing a tendency to come down first, counterpressure on the forehead through the vagina was kept up in order to produce flexion and cause rotation of the occiput on the pelvic floor. The advance was very slow; the patient became exhausted and the pains weak, and after two hours the forceps were applied and traction was made during

¹ Read before the section on obstetrics and gynecology, New York Academy of Medicine, March 20, 1896.

the pains. No anæsthetic was used. The head was brought down so as to bulge the vulva and stretch the perineum, and the forceps were removed, but the head retreated well into the pelvis after the subsidence of each pain. The cord was not around the neck. As no advance was made the forceps were reapplied, and strong traction delivered the occiput over the perineum and the face from behind the symphysis pubis. The mouth and nose were cleared of mucus. The child was cyanotic and made no effort at inspiration. Traction on the neck and efforts to produce rotation were of no avail. The cyanosis was increasing. Two fingers were introduced and the left arm was brought down, then the right arm, and by pulling and twisting the body was with difficulty delivered. Pulsation in the cord had ceased, and the heart could not be felt nor heard. Various means at resuscitation were resorted to, but not the slightest sign of life could be elicited.

Dr. E. A. Tucker informs me that the largest child out of four thousand delivered at the Sloane Maternity Hospital measured forty-three centimetres around the shoulders, or one centimetre less than the subject of this report.

The writer presents the mother for examination of the scar of the appendiceal wound, which has withstood so severe a strain as the weight of a child fifty centimetres long, in so stout a woman, and now at the end of two years shows no sign of hernia. This result speaks well for the single line of sutures in closing abdominal wounds.

10 WEST THIRTY-SIXTH STREET.

ACUTE UTERINE INVERSION.¹

BY WALTER LINDLEY, M.D.,

LOS ANGELES, CAL.,

PROFESSOR OF GYNECOLOGY IN THE MEDICAL COLLEGE OF THE UNIVERSITY OF SOUTHERN CALIFORNIA; PRESIDENT OF THE CALIFORNIA STATE MEDICAL SOCIETY, 1890, ETC.

THIS accident occurs only in about one case of confinement out of two hundred thousand, but as it is liable nevertheless to occur in the work of any general practitioner, I have felt justified in calling attention to my own recent experiences:

CASE: Mrs. C—; aged twenty-eight; primipara. The labor was normal but somewhat tedious. Position: L. O. A. Child, vigorous boy. I waited until pulsation ceased before tying the cord. The patient was in good condition and I waited ten minutes before taking any steps toward encouraging the progress of the third stage.

I then grasped the fundus through the abdominal wall and began using very moderate friction. The womb contracted for three or four minutes and suddenly, to my astonishment, disappeared. At the same moment the placenta popped out and there was alarming hemorrhage. Calling for a hypodermic of ergot and for hot-water douche I attempted to thrust my left hand into the vagina, but was met by a large tumor at the introitus. Like an electric shock the realization came to me that I had here to deal with an inverted uterus.

The hemorrhage being profuse, without loss of time I coned my left hand and dimpled the centre of the fundus with the coapted thumb and tips of the fingers, while making counterpressure through the abdominal wall with my right hand. By the steady pushing of the left hand, dropping the thumb out of the cone after a slight advance toward the cervix, the uterus was quickly returned to its normal relations.

While my ideas in regard to the length of time taken in this little operation are somewhat hazy, yet

it was probably from three to five minutes. The bleeding continued alarming and there was complete inertia of the uterine walls. The patient had already taken ergot hypodermically and by the mouth, and as quickly as the uterus assumed its normal position the hot water was turned into the cavity from a fountain syringe through a uterine irrigator; meanwhile I used friction through the abdominal wall with my right hand. It was all without avail. The patient's condition was critical. I then had six ounces of acetic acid added to three quarts of hot water, and almost synchronously with the first contact of the acetic acid I felt the uterine walls begin to contract. The contest was soon over, the uterine fibres again performed their functions, and the hemorrhage ceased. There was no laceration of the cervix. In a few minutes I repaired the lacerated perineum with silver wire.

The patient's recovery was rapid and uneventful, the only untoward symptoms being that on the third afternoon her temperature rose to 100° F. for two hours, and that her milk was so scanty she could not supply nourishment for the child. The restoration of the perineum was perfect.

If there had been any difficulty whatever in dimpling the fundus and pushing it quickly back, it would have been better to adopt the plan usually advised, of grasping the fundus in the hand and pressing upward on the sides with the fingers and thumb, thus, as the "American Text-Book of Obstetrics" says, "endeavoring to restore first that portion of the uterus which came out last." There are modifications of these two methods and the physician can doubtless readily see which plan is the best for the case in hand. When there is complete uterine inertia immediately following labor, the method adopted by me is simple, rapid, and easily executed.

In the *MEDICAL RECORD*, of October 26, 1895, is an interesting account of an operation by Drs. Davis and Packard for inversion of the uterus, which had existed for five days. The method adopted was this: The first step consisted of pressing the index and middle fingers firmly and steadily against the presenting fundus, at the same time making gentle counterpressure through the abdominal wall. "Gradually the uterine wall yielded, so that at the end of fifteen minutes the two fingers were buried in the tumor as far as the distal joint. The whole hand was now passed into the vagina and four fingers were pressed firmly against the mass, thus pushing it toward the cervix by continuous pressure, the elbow meanwhile resting on the bed as a point of support. With the help of the thumb, some degree of massage to the uterine walls was accomplished, with a view to rendering them more pliable and thus more tractable to further manipulations. Very soon the uterine walls began to soften, whether from the relaxing effect of the anæsthetic, or from the manipulations, or from both combined, and the cervix as felt behind the pubis grew appreciably softer. At the end of half an hour it was possible to carry the fundus before the four fingers fairly into the mouth of the constricting cervix, where they were steadily held as a wedge." This case differs from mine on account of the length of time after labor and the contraction of the uterus.

Gould's *Year Book* for 1895, quoting Jewett, says: "In a recent study of 100 cases of inversion Beckman found 54 occurred spontaneously, 21 after interference, and in 25 the cause was unknown. He believed the accident to be most frequent in primiparæ and in young women. In this series of cases there were 14 deaths. In two of the cases the uterus was irreducible, in 4 the reduction was spontaneous, in 61 there was artificial reduction, and in 119 hysterectomy was performed."

SPIRIT OF TURPENTINE IN THE TREATMENT OF BURNS.

DR. H. L. McINNIS, of Edmonton, Canada, writes: "Spirits of turpentine applied to a burn of either the first, second, or third degree will almost at once relieve the pain. The burn will heal very rapidly, much more so than by any other treatment that has come under my notice. I apply the turpentine as follows: After wrapping a thin layer of absorbent cotton over the burn, I saturate it with the turpentine and then bandage. The common commercial article is the one I use, as it is generally found in every house. Being volatile, it evaporates, and it is therefore necessary to keep the cotton moistened with it. When there are large blebs I open them on the second or third day. It is best to keep the spirit off of the healthy skin if possible, as sometimes pain is produced by its action. As I can find no mention of this treatment in the books I have, I take the liberty of sending this note, so that others who have greater opportunities may test the value of this treatment."

ACUTE MULTIPLE NEURITIS (BILATERAL) RESULTING FROM AN ATTACK OF DIPHTHERIA.

By MAJOR L. M. MAUS,

SURGEON, U. S. ARMY,
FORT SAM HOUSTON, TEX.

PRIVATE B. N—, Battery "F," Third Artillery, American, aged twenty, was admitted to hospital February 24, 1896, suffering from sensory and motor disturbances of both upper and lower extremities. He had been under treatment in the post hospital from the 3d to the 28th December, previous year, for a serious attack of diphtheria, contracted in San Antonio, the disease being quite prevalent there at that time. His condition on admittance was as follows: Numbness and delayed sensation of both feet and legs as high as the knees, and both hands and arms as high as the elbows; the paræsthesia almost amounted to complete anæsthesia. With the eyes diverted, he was uncertain as to whether a pin was introduced into his skin or not. Complete loss of tactile sensation. There was also paræsthesia of the chest surfaces, paresis of the flexors and extensors of both upper and lower extremities, with complete loss of the cutaneous and tendinous reflexes. The gait was shuffling and very uncertain; he could move slowly, dragging his feet along, exhibiting marked paresis of the extensors. The skin was cold and moist over the affected areas. The line of demarcation between the parts affected and the non-invaded areas was well marked by the sensory symptoms and the surface coldness just referred to. He was suffering from no special pain or increase of temperature. The thermometer recorded 99° F. under the tongue and the heart beat was slightly under 100, the latter probably resulting from exercise in reaching the hospital. Diminished electro-contraction was also noted, with marked pain upon the application of the faradic current. The patient's statement was as follows: That he first experienced a sense of weight and heaviness of feet and hands, which was quickly followed by numbness and tingling of the same parts about three weeks before entrance into hospital. The numbness began in the toes, extending to the ankles and finally to the knees within a few days. About one week after the numbness started in the toes, it began in the fingers and rapidly extended to the elbows. There was more or less pain, though not severe, from which he concluded that he was suffering from rheumatism. It appears that the attack was not preceded by fever. Motor disturbance began when the numbness ascended as high as the ankles, and he

was hardly able to walk when it had reached the knees. He states that during drill he could scarcely grasp the corporal's hand (he being No. 3) when the order, "Prepare to mount," was given, and was unable to grasp the trail of the piece at the order, "Prepare to limber or unlimber." Private N— is quite young, had during the past year been in the hospital several times, and, being sensitive for that reason, failed to present himself for treatment until he could go no longer. The similarity of symptoms between multiple neuritis (polyneuritis) and ascending paralysis (Landry's disease) frequently render a diagnosis between these two diseases difficult, and indeed it is said by certain authorities to be quite impossible at times. I would infer from the literature on the subject that there are those who regard these diseases as identical. Both diseases are certainly quite uncommon in general practice, and extremely so among soldiers. I do not recall a single case of either before in my army experience. Upon the patient's admittance into the hospital, therefore, the question as to the true nature of the disease naturally presented itself, whether we had a Landry paralysis or a case of multiple neuritis to deal with. It will be observed from a comparison of the following two paragraphs that a marked similarity in the symptoms of the two diseases exists, sufficiently distinct, however, when the two diseases are typical cases, for a diagnosis.

Acute Multiple Neuritis.—The disease usually begins suddenly with fever and symptoms of an acute infectious disease, is accompanied by sharp burning or tearing pains. This is soon followed by sensory symptoms, such as formication, tingling of the toes and fingers, and numbness which advances into paræsthesia or complete anæsthesia of the affected parts. Paresis of the flexors and extensors of the arms and legs soon merges into complete paralysis. There is loss of or diminished faradic contractility. The paralysis as a rule extends from legs to arms before the trunk is invaded. Coldness of the surfaces of the affected parts is a prominent symptom in multiple neuritis. The later symptoms are trophic changes in muscles affected, skin, nails, and hair; œdema of the hands and feet; albuminuria and enlarged spleen. The patient may die in a week from paralysis of the respiratory muscles, or the disease may terminate in recovery after weeks or months.

Acute Ascending Paralysis (Landry).—Slight fever the first few days; pain in toes, fingers, and back first few days, accompanied by weariness and general discomfort. Sensory symptoms are usually absent, though slight tingling, numbness, and hyperæsthesia have been observed in toes and fingers. Actual paralysis soon supervenes, involving feet, legs, thighs, arms, and trunk. The muscles of articulation, deglutition, and respiration are generally affected. The paralysis may begin in upper extremities. The patellar reflexes are sometimes obliterated. Electrical reaction remains normal. No trophic changes occur in muscles, skin, nails, or hair. Death may occur within a few days, or the disease may continue for months and the patient finally recover.

As a rule there is a marked difference in the sensory symptoms; numbness, tingling, formication, paræsthesia and anæsthesia are always present in multiple neuritis and rarely so in ascending paralysis. The disease usually begins with fever and simulates the attack of an acute infectious disease in the former, which is not the case with the latter. This was not the case with Private N—. The electrical reactions are different in the two diseases and trophic changes do not occur in ascending paralysis. The paralysis in multiple neuritis usually begins in the feet and legs, then advances to hands and arms. In ascending paralysis the paralysis extends from the legs to the

trunk before the arms are involved; this symptom is variable. However, there are many exceptions to be noted, both in the march of the paralysis and as well in the sensory symptoms. Both diseases may terminate fatally within a few days from paralysis of the respiratory muscles, or both may go on to a tedious recovery.

When sensory symptoms are present in ascending paralysis, the diagnosis between that disease and multiple neuritis then becomes very difficult.

Pathology.—In acute multiple neuritis we find degeneration of the medullary sheath and axis cylinders of the nerve fibres. At first we find them swollen, divided into segments of a semifluid consistency. In more severe cases, the medullary sheath is broken up into fine granules of fat or molecular debris, which are absorbed. The axis cylinders may be not only swollen but also changed into a granular mass, which may be completely absorbed, so that an empty sheath of Schwann alone remains as a trace of a former nerve fibre. As recovery occurs, regeneration of the nerve fibres takes place. Dr. Starr is authority for the above pathological statements.

In acute ascending paralysis we find myelitis of the motor tracts of the cord of the anterior gray matter and of part of the medulla oblongata. The myelitis may be chiefly of the antero-lateral columns in the cervical and dorsal regions (Zenner). Hun states that Landry's disease without sensory or bulbar symptoms must be regarded as a clinical entity for which no corresponding lesion has yet been discovered.

The following history of this very interesting case has been taken from the hospital records:

The general condition of the patient remained excellent. His mind was clear, he was free from pain when undisturbed, his appetite was excellent, and he slept well. The paralysis of arms and legs became complete within several days after admittance. Numbness and anæsthesia of the affected parts remained unchanged until March 3d, when slight symptoms of returning sensations were observed. About this time he suffered considerable pain in the knee-joints. The temperature, taken morning and evening, was normal, and the pulse rate ranged from 60 to 84. March 4th, hyperæsthesia over arms and legs was complained of; the patient stated that he experienced a sensation similar to that of striking the ulnar nerve over the elbow-joint whenever anything touched his skin. He suffered from extremely cold hands and feet during the first three weeks after admittance into the hospital, so much so that the application of hot-water bottles became necessary for weeks. He was allowed to sit up March 23d, and was rolled about in an invalid chair. There were no marked changes in motor or sensory disturbances until March 27th when the sensation of numbness and hyperæsthesia suddenly disappeared.

April 5th the patient began to walk with a shuffling gait and at this time had slight control over the extensors and flexors; there was still complete loss of the skin and patellar reflexes and more or less diminished loss of faradic contractility. His anal and vesical sphincters remained unimpaired throughout the entire sickness. The treatment consisted of good nutritious diet, applications of heat, and iodine painted over affected parts. Later iodide of potassium and electricity were used.

April 16th walking was improved; he still experienced delayed sensation over both feet, legs, hands, and arms. More or less paresis of the flexors and extensors existed. He stated that his sense of touch was keener in the right arm and left leg than in the left arm and right leg at this date.

April 24th improvement in walking continued; he had better control over flexion and extension of both upper and lower extremities. He stated that there

was less delayed sensation in the left arm and right leg than in opposite arm and leg.

April 28th the patient was able to walk naturally, but still experienced slight delay in sensation over the affected parts. He said he was able to perform his duty. I regard him as virtually recovered, and but for the removal of a congenitally elongated prepuce, which was done April 25th, would return him to duty.

CONGENITAL OCCLUSION OF THE URETHRA.

BY THEO. G. DAVIS, M.D.,

BRIDGETON, N. J.

THE report of a case by Dr. Allen in the *MEDICAL RECORD* of June 6, 1896, recalls the case of a female child born in September, 1885, who did not pass urine for three days, when my attention was called to it. On examination no urethral orifice or urethra could be found, but by inserting my little finger into the vagina, about an inch and a quarter, there could be found a fluctuating body, evidently the distended posterior urethra. With a finger in the vagina as a guide, a small trocar was thrust through the tissues where the urethra should have been and a small catheter was passed through the cannula into the bladder, where it was retained for four days, the urine being passed through it until it was removed and then through the wound made. The girl is now eleven years old and has always had perfect control over urination.

ARREST OF SMALL-POX IN ITS VESICULAR STAGE.

BY F. S. FURMAN, M.D.,

SHREVEPORT, LA.

IN the *MEDICAL RECORD* of July 18th there was an article by Dr. Alonzo Bryan, of Detroit, Mich., entitled "Arrest of Small-pox in its Vesicular Stage." In this article the doctor alludes to a paper read by him at a meeting of the Detroit Medical and Library Association, in which he maintained that the eruption of true small-pox extends to and includes only the vesicular stage, and that the vesicles are simply infection atria through which pus germs and saprophytes are intromitted to the structure of the true skin and to the general system.

The paper claimed that the germs of suppuration and of putrefaction are lying in wait, embedded in the epidermis, ready to commence their ravages upon the true skin and system at large as soon as their liberation is effected through the instrumentality of the maceration of the epidermal layers by the fluid of the vesicles.

Furthermore, he declared it as his opinion that the aforesaid pathological germs might be forestalled in their pernicious action by means of germicidal fluids applied to the general surface of the body, whereby a complete maceration of the epidermis could be effected.

To accomplish this object, he proposed baths of long duration in antiseptic fluids. In a word, he suggested the cautious and gradual evolution of a system of disinfection to be applied to the entire epidermal covering; and when the epidermis was disinfected it was to be kept aseptic by means of suitable antiseptic dressings applied to the cutaneous surface until the complete desiccation of the vesicles.

By means of such a course he proposed to arrest the small-pox in its vesicular stage, and completely prevent suppuration of the skin and suppurative fever with its various dangerous complications.

This paper was never published, and the first reference I saw to it was in Dr. Bryan's article in the *MEDICAL RECORD* of July 18th. The doctor goes on

to report a case of discrete small-pox treated by him in the small-pox hospital at Detroit, in which the treatment was entirely local and was successful in arresting the small-pox in its vesicular stage.

I shall report two cases of small-pox treated by me last spring, in which the treatment, though differing slightly in some particulars from that adopted by Dr. Bryan, was yet the same in essentials, in that it was directed to the local treatment of the vesicles and had for its object the prevention of the transformation of the vesicles into pustules.

The first case was one of varioloid. The patient had been recently vaccinated, and though the temperature reached 104° F., not over one hundred papules appeared over the entire surface of the body.

As soon as the papules developed into vesicles I scrubbed the surface first with soap and water, followed by peroxide of hydrogen; I then opened the vesicles, allowing the contained fluid to escape, and taking a soft-wood splinter sharpened to a point, I first dipped it into liquid carbolic acid and then introduced it into the cavity of the vesicle. The surface of the skin was again washed with peroxide of hydrogen and oiled, to relieve the smarting caused by the application of the carbolic acid; after this the surface was covered, wherever practicable, with cloths wrung out in carbolyzed water.

The patient's temperature was taken frequently, and was never found to be above normal after the stage of invasion.

In this case only two pustules were developed—one in the hair before the treatment was begun, and one on the tip of the nose, which owing to its location was not properly protected.

My second case was one of discrete small-pox, which came under my treatment during the vesicular stage. In this case too much surface was involved for me to use the carbolic acid as freely as I did in the first case, so I treated it on a plan more in accordance with that adopted by Dr. Bryan.

After thoroughly washing with soap and water and peroxide of hydrogen, I opened the vesicles, and then washed the surface with a ten-per-cent. solution of carbolic acid. I should say, however, that there were about ten or twelve pustules which I opened and after removing the pus treated with carbolic acid, as I did the vesicles in my first case. When I began my treatment the temperature was 102° F., and six hours later it was normal and continued so until the patient was discharged. The disease immediately went to the stage of desiccation.

In neither of these cases was there any pitting, except from the pustule on the tip of the nose in the first case.

My first case was such a mild one that there is a question whether or not there would have been any secondary fever had the patient received no treatment at all; but in the second case there is no doubt in my mind that the secondary fever was prevented by the treatment.

I have reported these two cases, as I believe they are further proof of the truth of Dr. Bryan's theory quoted in the paper mentioned above. I am sorry it was impossible for me to use this treatment in a case of more virulent type of small-pox, but in view of its success in my second case and in the case treated by Dr. Bryan, both of which were discrete, I should not hesitate to use it where more surface was involved; modifying the strength of the antiseptic fluid used according to the extent of surface involved.

As to the kind of antiseptic used, that would, of course, be merely a matter of preference on the part of the physician, as we would not hope for specific action of mercuric bichloride, carbolic acid, or other antiseptic beyond their germicidal action.

PNEUMONIA COMPLICATED WITH FATTY TUMOR IN THE RIGHT AURICLE.

By JOS. L. SPRUILL, M.D.,

BALTIMORE, MD.,

ASSISTANT RESIDENT PHYSICIAN, ST. AGNES HOSPITAL.

C. G.—, German, aged twenty-three, came to St. Agnes Hospital Dispensary (Baltimore), suffering from well-marked acute lobar pneumonia in its first stage, having had the initial chill about twenty-four hours previously. He was at once taken into the hospital.

The patient was a strong, robust man, giving a history of good health all his life, but said he was an habitual drinker. The temperature was 101° F., pulse 120, general condition good. The patient seemed to do well for three days, the case not being one of unusual severity, with the exception of high fever, which at one time reached 105° F., falling about three degrees, however, when cool sponging was resorted to. His pulse, respiration, and general condition remained good, and he took quite an amount of liquid food.

At the beginning of the second stage of the disease, the patient was put on stimulating treatment, his case seeming favorable until the fourth night after admission. At 9 P.M. he expressed himself as feeling very well and soon dropped into a quiet sleep. Three hours later his condition was still good, temperature being 102.5° F. and pulse fair. At 2 A.M. he began to show marked signs of heart failure. The extremities became cold, the face and lips pale, the pulse rapid and feeble, failing to respond to repeated hypodermic injections of brandy, strychnine, and digitalis. Patient died one hour later.

Post-mortem examination showed the lung extensively involved, and upon opening the heart a peculiar fatty growth about the size of a large walnut was found in the right auricle, firmly attached to its walls and requiring dissection to remove it. Microscopical examination showed the growth to be of fatty structure.

SNAKE BILE FOR SNAKE BITE.

By L. S. ALEXANDER, M.D.,

ST. AUGUSTINE, FLA.

SOME months ago I saw an article in one of the New York journals concerning the treatment of snake bite with the bile and flesh of the reptile. Having seen the failure of other remedies, I determined to make use of this suggestion at the earliest opportunity. Consequently I directed a taxidermist of this city who had on hand a number of rattlesnakes to prepare a gall bladder for use in an emergency. On or about the 12th of June the same taxidermist, an aged man, was struck on the inside of the left knee by one of his large rattlers. Immediately disposing of the snake, he proceeded to examine the wound, which was bleeding freely. Suction by the mouth, a milking or strapping process with the fingers, with a hunt for and application of some household ammonia, must have taken several minutes before the bottle of bile was thought of. This was applied freely to the wound, and an incision was also made into which the bile was poured. It was probably half an hour before he reached my office, apparently all right but a little anxious. I continued the application of the bile and covered the wound with a piece of the wall of the gall bladder. No other treatment was pursued beyond a few doses of carbonate of ammonium. There was not one particle of swelling, nor did the man suffer from inconvenience of any kind.

Therapeutic Hints.

Rheumatic or Muscular Pains.—

R Chloroformis puræ..... ʒ v.
Tr. opii,
Acidi salicylici āā ʒ iv.
Spts. vini rect. ʒ iv.
Olei dulcis q.s. ad ʒ xij.

This should be rubbed into the parts thoroughly or applied by means of flannel cloths.—MANLEY.

Follicular Tonsillitis.—

R Olei creosoti..... gtt. viij.
Tinct. myrrhæ,
Glycerini āā ʒ ij.
Aq. ad ʒ viij.
S. Use as a gargle every two hours.

—DR. LEVY, *Medical and Surgical Reporter*.

Pain of Gastric Ulceration.—

R Exalgin gr. xlv.
Extract of belladonna,
Codeine phosphate.....āā gr. v.
Sugar of milk..... gr. lxxv.

Mix and divide into ten cachets. Dose, one to be taken with the onset of pain.

—DR. BOAS, *Semaine Médicale*.

Cough Mixture.—This prescription, given in the pharmacopœia of the Edinburgh Royal Infirmary, contains no opiate:

R Acid. hydrocyan. dil ʒ ss.
Acid. nitric. dil ʒ iij.
Glycerini ʒ i.
Inf. quassie ad ʒ vi.

Ft. mist. S. A tablespoonful in a wineglass of water three times a day.

It is both a sedative and tonic in cases of phthisis.—DR. WARBURTON BEGGIE.

Whooping-Cough.—

R Infusion of belladonna leaves (gr. viij.) in
distilled water..... ʒ v.
Antipyrin gr. xv.
Syrup of gooseberry ʒ i.

M. S. A teaspoonful every two hours for a child of five years.

As a rule there may be given, for each year of the child's age, gr. viij. of belladonna leaves in infusion and the double dose of antipyrin.—DR. ESCHLER, *La Médecine Moderne*.

Gonorrhœa.—

R Perchloride of mercury 1
Antipyrin 100
Distilled water..... 10,000

The injection should be used four times a day and retained as long as possible. The addition of antipyrin prevents smarting.—DR. VATIER.

To Prevent Iodism.—It is claimed that the following may be given indefinitely without causing iodism:

R Potassii iodidi..... ʒ iss.
Ferri et ammonii citratis..... ʒ ij
Tinct. nucis vomicæ ʒ ij.
Aque ʒ iss.
Tinct. cinchonæ comp..... ʒ ij.

S. Teaspoonful three times daily, in water, after meals.

—SANDERSON, *Medical Weekly*.

Pulmonary Tuberculosis.—Dr. Otis (*Boston Medical and Surgical Journal*, May 29th, p. 527) says: "In every well-arranged plan of treatment of pulmonary tuberculosis, when any exercise at all is allowable, pulmonary gymnastics, carefully arranged and adapted to the strength and condition of the individual, should, I believe, be embraced. In the famous sanitariums

abroad, where such excellent results are obtained, they play an important part in the treatment. We may in the future obtain a serum product which will accomplish all that was hoped for from tuberculin; but one must not forget that large numbers of consumptives are now being cured and restored to usefulness by means of the persistent application of nature's remedies, sunlight, abundant alimentation, continuous outdoor life, hydrotherapy, and good breathing. The vis medicatrix naturæ may not always give brilliant and rapid results, but when intelligently employed it is a method which rarely disappoints either the confiding physician or trusting patient."

Malarial Hæmaturia.—Keep the bowels open with calomel followed by salts, use hot mustard baths, and administer the following combinations in alternation every three hours:

R Spirit. turpent..... ʒ ij.
Acidi carbol..... gr. x.
Pot. chlorat..... ʒ iij.
Spirit lav. comp..... ʒ ij.
Acacia gum..... ʒ ij.
Aqua. menth. pip.....q.s. ad ʒ iv.

—DR. J. E. LONG, *Louisville Medical Monthly*.

Diarrhœa.—A serviceable prescription in cases of watery diarrhœa due to exposure, or exhaustion, or an irritant food, etc., is as follows:

R Acid. sulph. aromat..... ʒ ss.
Olei cajuputi..... gtt. xl.
Fl. ext. hæmatoxylin ʒ ij.
Spt. chloroformi ʒ i.
Syr. zingiberis.....q.s. ad ʒ iij.
M. S. Teaspoonful in water every two or three hours.

—*College and Clinical Record*.

Adherent Pericardium.—Dr. Broadbent (*Boston Medical and Surgical Journal*) publishes the notes of four cases, in each of which there was visible retraction, synchronous with the cardiac systole, of the left back in the region of the eleventh and twelfth ribs, and in three of which there was also systolic retraction of less degree in the same region of the right back. In all the cases there was a definite history of pericarditis, and in three of them there were other conditions strongly suggesting an adherent pericardium. The only means of causing this retraction on both sides seems to be the diaphragm, which, if pulled upon, would have more effect upon the floating eleventh and twelfth ribs than upon the more fixed ones. In cases of large heart with adherent pericardium there is a considerable area of the ventricle closely adherent to the central tendon of the diaphragm, and the powerful contraction of an hypertrophied heart must give a decided tug to this structure. That it should affect the ribs more often on the left side ought to be expected, since the adhesions are mainly to the left of the median line, while the liver, which is often large in these cases, may restrain the movement on the right. Apart from the adherent pericardium one was a case of aortic disease of rheumatic origin, the others of mitral disease.

Cold Bathing during Menstruation.—Cold bathing during menstruation is a beneficial measure, provided women become accustomed to it by bathing every day for eight days before. Henzel holds that cold salt-water baths facilitate the menstrual flow, increase the duration of genital life, and increase fecundity.—DR. DEPASSE, *Lancet-Clinic*.

Japanese Physicians do not look with favor on the bicycle, and regard its use as injurious to both men and women.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ELECTIONS TO THE MEDICAL COUNCIL—THE REPORT OF THE ROYAL VACCINATION COMMISSION—THE REPORT OF THE ADULTERATION COMMITTEE—WATER FAMINE—GLOUCESTER—GRANT BEY'S DEATH.

LONDON, August 21, 1896.

THE plot thickens as to the elections to the medical council. For the three vacancies there are more than double that number of candidates, all of whom may be said to have some points in their favor. Dr. Glover seems to have completely amalgamated with Drs. Woodcock and Drage, who are supported by the British Medical Association. Thus we have once more *The Lancet* and the *British Medical Journal* rowing in the same boat. Perhaps this partly accounts for the compliments these journals have recently exchanged, which not so long ago would have been deemed impossible. At the last meeting of the Association of Fellows of the Royal College of Surgeons it was resolved that Mr. Walter Rivington be invited to become a candidate and that the society of members should be asked to join in this invitation. Mr. Rivington is one of the liberal councillors of the college and has a long record as an able medical reformer. He is also on the senate of the London University, of which he is a graduate in arts as well as in medicine. He has taken an active part in the movement to redress the wrongs of Dr. Anderson, of whose case I have written more than once. This and the question of representing members in the council of the college are the chief reasons for the Association of Fellows proposing him, but his other qualifications are of the highest. Those who feel unwilling for the British Medical Association to permanently "nobble" the direct representatives and so to resent Dr. Glover's conduct in facilitating such a result, will be able to plump for Mr. Rivington and thus express their sentiments while voting for a sound and sincere reformer.

Distant as the election still is, the signs of a coming contest increase. Candidates have rivalled each other in condemning the council for its shortcomings, and of course implying that their election would tend to inaugurate a new era. At last one of the councillors has entered a defence. Mr. Brudenel Carter, who represents the Apothecaries' Society and whose journalistic position gives him great influence and unusual scope for his literary ability, has written a letter in which he examines somewhat cynically the claims of the candidates, and puts questions as to how they could improve matters as naively as if he really thought the council quite a model body. But he is not content with this method of defence, and, perhaps with a view to draw his opponents, casts scorn on agitators and dangerous persons, sneers at the literary quality of some addresses, and pronounces others "balderdash." Candidates and their champions have no hesitation in picking up the gauntlet thus thrown down. Mr. Victor Horsley is to the front, and exposes without mercy some errors of Mr. Carter's, and assures him he "cannot be credited with a ten-years' useful service, on which he is inclined to plume himself." Mr. Horsley had a paper at Carlisle, in which he impugned the regulations of the council and the acts of its president. This he intimates will shortly be published in full, and he challenges Dr. Carter to refute any of his statements. So further developments may be anticipated.

Dr. R. Rentoul, who is one of the candidates, has found out that the registered practitioners in the Isle

of Man are not considered entitled to vote at the election. He wants to know if the Isle of Wight is also disfranchised. The act provides for the election of three representatives by practitioners resident in England, one by those in Ireland, and one by those in Scotland. It is strange if the adjacent islands of the three kingdoms are not to be included. Perhaps the Isle of Man, having a certain local government of its own, is considered by the council as a separate State. The matter will probably be submitted to the privy council, and we shall then learn whether islands are not in legal phraseology embraced in the name of the country to which they belong. Assuredly the islanders are required to obey the laws of the kingdom.

At last the report of the commission on vaccination has appeared. Whether it is worth the seven years' incubation is a question with many. Perhaps the answer must be left until we see what legislation may be carried. The recommendations are in effect to make vaccination more attractive to the people and to render compulsion less stringent. The report recommends that the age during which the operation is obligatory should be extended from three to six months, which is the Scotch limit. The commissioners do not advise the substitution of other forms of punishment for pecuniary penalty. They do not consider it feasible to hand over the duty of enforcing the law to county councils, nor to vest in the local-government board the duty of proceeding against defaulters. They consider it would be advisable to devise a scheme permitting parents who are honestly opposed to vaccination to escape, but not those who are merely indifferent or negligent. They suggest that the parent might be required to attend before the local authority and satisfy them of his honest objection, or a statutory declaration to that effect might be demanded. Any plan of the kind, it is admitted, should be such as would not be adopted merely to save trouble connected with the operation. It seems to me that such proposals to give the parent a little trouble can operate no more effectually than the fine at present imposed. If adopted only after the first fine had been paid, the plan would be an excuse for not inflicting more than one fine in one case. The commissioners think it would promote the practice of vaccination if the fee payable to the public vaccinator were to be paid to every qualified practitioner who performed the operation, and they advise a system of inspection to secure that the prescribed rules should be observed in such cases. They think persons committed to prison for non-compliance with the vaccination laws should not be treated as criminals.

Sir Guyer Hunter and Mr. Hutchinson, while agreeing in the main with their fellow-commissioners, append the following memorandum to the report: "We are not able to recommend such a large relaxation of the compulsory law as is implied in the paragraphs dealing with compulsion. We think that no further change should be made than to allow a magistrate, before whom any one refusing vaccination has been summoned, to abstain from inflicting fine if satisfied on the evidence given on oath that the objection was one of conscience. We also think that notwithstanding the difficulties set forth in the paragraph dealing with revaccination, that operation at the age of twelve should be made compulsory."

From the foregoing it will be seen that the commissioners admit the protection afforded by vaccination, and the agitators will obtain little comfort from the report. The commissioners state that it not only diminishes the liability to attacks of small-pox, but that it renders the disease less fatal and less severe. They also state that the protection diminishes with time, and therefore revaccination is desirable. They admit some dangers, although in relation to the extent of the

work they pronounce them insignificant. As a security against dangers they would give parents the right to demand calf lymph.

From these brief notes culled from its pages it will be seen that this heavy blue book, which has taken seven years to produce, confirms most of the opinions of the profession, putting them only in as mild a way as possible. Lukewarm advocates will be satisfied and agitators discouraged, while the few honest faddists are to be allowed to hold their foolish prejudice and keep in a protected community a family which, being unprotected, is by so much a public danger.

The report of the committee on the adulteration acts is rather encouraging, but will not quite satisfy sanitarians. Still, if all the recommendations could at once become law, adulteration of food and physic would be more risky and therefore less profitable. The report acknowledges that the undue leniency of magistrates has made it worth while for the dishonest to go on adulterating and paying the fines when caught. Heavier penalties are recommended and the offenders are to be made to publish their convictions in the local newspapers. It is also recommended to define the word food so as to include flavoring or other ingredients. This would prevent adulterated baking-powder longer escaping on the plea that it is not a food. On the other hand, it is not proposed to enforce a statement on labels of mixtures as to the proportion of ingredients, so that a "mixture of chicory and coffee" may contain ninety or more per cent. of the "cheap and nasty." The most important recommendation of the committee is that a court of reference should be formed which shall settle the limits and standards of the quality and purity of articles of food. It is further advised that the local authorities should take for examination a larger number of samples yearly, and that these samples should not be taken by officers well known to the tradesmen.

The water famine in the east of London is still a public danger. The breakdown of the East London Water Company will probably greatly increase the demand to terminate the monopolies of the companies.

The Gloucester epidemic of small-pox is considered at an end, after a record of more than two thousand cases.

The death of Dr. Grant, better known as Grant Bey, who did distinguished service in Egypt, is regretted by all who take an interest in that country and especially in its sanitary progress. He was a scholar of wide learning and had received many distinctions.

DISCRIMINATING TREATMENT OF APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The appendicitis question will not down so long as the extremist, in a presumably laudable effort to show the general practitioner the error of his ways and to save him from the wrath to come, continues to insist that every case of appendicitis must be operated upon immediately, and the general practitioner obdurately refuses to accept this dogma. When the specialist impugns his statistics, denies his diagnostic ability, and in his delightfully modest way suggests other sources of pain in the right side of the abdomen, the general practitioner bears it with becoming meekness, knowing that in the eternal fitness of things the account will soon be balanced, in that he will not be able to advise the removal of the appendix if incapable of recognizing the disease which demands its ablation.

The extremist makes the assertion, regardless of its absurdity, that but from nine to fifteen per cent. of appendicitis cases recover under medical treatment.

Since he operates on all of his patients, his information apparently does not come from personal experience and may be taken with the customary modicum of sodium chloride. In this connection Dr. Woods' article in the MEDICAL RECORD of August 22, 1896, furnishes valuable information and, written from the standpoint of the insurance company, is undoubtedly free from bias.

The operative surgeon informs us that after medical treatment relapse will occur in the vast majority of cases. We maintain that, under the opium treatment favoring localized plastic peritonitis, relapses are infrequent. Dr. Morris says that some of my twenty-four cases "are not very well since their recovery," which leads me to wonder if Dr. Morris has information, other than purely theoretical, in regard to my cases which I myself do not possess, or whether he states this on the principle that if the facts do not accord with the theory so much the worse for the facts.

The apostle of operative procedure claims that medical treatment does not cure in these cases and holds up before our rapt vision the prospect of a safe, sure, and permanent cure. But in a liberal proportion of cases the appendix is not removed at the time of the operation. Can he then consistently claim that his patient is cured, ay, sugar-cured, plus the liability to a troublesome ventral hernia?

The operative expert communicates to us in due and ancient form the assertion that cases in country practice in which the person cannot pay a surgeon or cannot be removed to the hospital need but seldom occur. We who are familiar with the sordid poverty of many of these patients, the niggardly policy of our poor officials, the wretched roads, the snow blockades, the prejudices of such people who are apt to consider the hospital a sort of terrestrial gehenna, and the absolute refusal of many of these patients to be cut open—we would like the expert to explain how the necessary funds are to be obtained, the objections set at naught, and the desired end accomplished. If an operative surgeon is summoned he will expect to be recompensed. But the "fee does not enter into the controversy and is unworthy of being mentioned by an honorable practitioner." The said honorable practitioner should quietly dip his hand down into his pocket to pay it and perhaps forego a post-graduate course in operative surgery in New York or other uttermost parts of the earth in consequence. On the other hand the local surgeon, if he works with an eye to his patients' interests rather than his own, having only a moderate experience in abdominal surgery, will operate on appendicitis cases only when stern necessity compels.

The operative propagandist has an alluring way of contrasting the brilliant records of our most expert operators in well-equipped hospitals with some very doubtful statistics of results under medical treatment. Of what value is this in the question at issue? That surgical treatment for city and suburban cases is eminently successful was established long before this controversy arose. A contrast of the average results from surgical and from medical treatment would be to the point, and when the results of operations performed by the average surgeon throughout the country are supplemented by the results of cases in which patients have been ripped open by the tyro with more zeal for surgical fame than regard for human life the mortality will be found very high.

The real questions at issue are:

- 1st. What is the best treatment for outlying cases?
- 2d. What proportion would recover if treated medically?
- 3d. What proportion would relapse?
- 4th. What proportion of these cases if operated on under existing conditions would recover?

5th. What proportion would relapse?

6th. How shall we select the operative from the non-operative cases?

In deciding these points neither dogmatic assertions nor brilliancy of satire will count. What we need are facts—facts, which at best are stubborn things. My own contribution to this subject is that I have furnished twenty-four facts in the twenty-four consecutive cases which recovered under the opium treatment—facts which seem to have aroused the ire of some of my brethren.

In order to decide these points many statistics from private practice must be furnished. I still hold to my conviction that had I, since the beginning of my practice, adopted in all of my cases either an exclusively medical or an exclusively surgical treatment, I should have lost some of them, while as it is I have yet to record a death from appendicitis. I do not pretend to lay down any rule as to when operation is or is not indicated. These questions are largely questions of judgment, of most excellent judgment in the individual case, and I would suggest to some of our specialists that the exercise of this faculty should not be held in suspension or abeyance, should not be limited in its application by any inelastic and arbitrary rule, to merely a choice of operators or the most favorable time for slitting the abdominal parietes.

A writer in the MEDICAL RECORD of June 13th says that euthanasia will be a *fait accompli* "as soon as the opium treatment shall be regularly adopted" in gangrenous, perforative, or acutely suppurative appendicitis. "Gently and with Christian resignation," to use his own words, I would "point out to him" that having neither a "very pretty talent for mathematics" nor for "the gentle art of embroidery," as he so freely acknowledges, he should not heedlessly attempt to show that "two and two make six," by implying that I have ever advocated that the opium treatment should be "regularly adopted" in all cases, a position which I should attack were it necessary as earnestly as I do the other extreme. It is the extremist who exposes himself to attack, it is the extremist whom I attack, and it is the extremist who, aside from his proneness to err, exhibits at least one other human trait—he squeals when he is hurt.

What manner of man is the surgical enthusiast? Will he never be content? We do not deny the necessity for operative procedures in many cases. When he shows us a brilliant record of successful operations we applaud his success, we acknowledge his merit, we admire his skill, we marvel at his beautiful, not to say pulchritudinous dexterity, we even buy his books—and read them; but when this same enthusiast, unmindful of the history of the clitoridectomy fad, the oöphorectomy fad, the multitudinous other fads in fashion for lo, these many years, unblushingly demands that the general practitioner yield up every case of appendicitis to the goddess of the knife, we, the general practitioners, not entirely oblivious to nature's reparative power, backed up by a host of eminent surgeons, with a vivid memory of fads which have come and of fads which have gone, rise up and answer emphatically, NO.

W. N. MACARTNEY.

FORT COVINGTON, N. Y., August 15, 1896.

A Sign of Death.—Dr. G. H. Brandt, writing to the *British Medical Journal* with reference to the application of heat in cases of suspected death, sends the following mode of application: Light a wax vesta, apply the flame close to the skin until a blister is formed; if it contains serum the person is still living; if, on the contrary, it contains only gas, it will burst with a small explosion and life is extinct.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 29, 1896:

	Cases.	Deaths.
Tuberculosis.....	174	100
Typhoid fever.....	15	6
Scarlet fever.....	24	2
Cerebro-spinal meningitis.....	0	2
Measles.....	30	5
Diphtheria.....	131	18
Small-pox.....	0	0

Isn't it a Wart?—Dr. X— begins a communication to a contemporary: "I have on hand an enlarged prostate."

"Keep thy heart above all that thou guardest, for out of it are the issues of life," is an injunction nearly thirty centuries old, yet it is still a maxim as pregnant with wisdom for us in the treatment of the sick man as many a more modern dictum.—EMERSON.

A Human Crazy Quilt is what a girl in San Rafael, Cal., calls herself. She has been covered with skin grafts taken from numerous friends, to cover the results of a severe burning accident. It is said that she makes careful note of the location of each friend's contribution for future reference.

Slobbering.—Dr. Sanchez de Slivera (*Lo Sperimentale*) concludes that healthy infants never dribble. Infants that dribble only in the daytime, though apparently in good health, have their digestive functions impaired. Infants that dribble at night are suffering from obstruction of nasal respiration. These phenomena are altogether unconnected with dentition.

High-Altitude Treatment.—Dr. Mays (*New York Medical Journal*, June 27, 1896) writes as follows: The ever-recurring question is: Should patients with a disposition to blood spitting be sent to high altitudes? From a theoretical standpoint I think many objections may be raised against such a change, but practically I believe that high altitudes have no detrimental effect on this condition; on the contrary, it seems that nearly all such cases derive benefit from this kind of treatment.

Prevention of Conception.—I dare any political economist to show me one expedient whereby conception may be avoided. I challenge him to name a single preventive which will not do damage either to good health or good morals. Even natural sterility is a curse. Show me a home without children, and ten to one you show me an abode dreary in its loneliness, disturbed by jealousy and estrangement, distasteful from wayward caprice or from unlovable eccentricity.—DR. WILLIAM GOODELL.

Gastric Ulcer.—Dr. Williamson (*Physician and Surgeon*, July, 1896) recommends: 1. Absolute rest in bed. 2. Laxative saline mineral waters and rectal alimentation. Later on liquid nourishment and after three weeks a more generous diet; tonics, preferably the hypophosphites at first, owing to the liver's inactivity usually, and iron preparations subsequently, along with arsenic, which is one of the best. For gastralgia—anodynes, especially morphine. For hemorrhage—absolute rest, ice, morphine, and ergotin hypodermically.

A New Complaint.—"Is there any particular nervous complaint connected with your profession?" asked the cheerful idiot of the rifleman. "There is the tennis arm, the bicycle face, and the baseball arm, and I thought there might be something of the sort among you gunners."

"No," said the rifleman; "nothing of the sort."

"It is very queer," said the cheerful idiot thoughtfully. "I didn't suppose you could hit the target without taking sharpshooting pains."—*Indianapolis Journal*.

Menstruation in Eskimos.—Dr. Cook, who was with the Peary expedition, says the Eskimo girls do not begin menstruating until they are eighteen or twenty years of age.

Odor a Symptom of Disease.—Dr. McCassy (*Lancet-Clinic*) writes as follows: Diseases have their characteristic odors. Insane asylums have a familiar odor. Favus has a mousey odor; rheumatism has a copious, sour-smelling, acid sweat. A person suffering with pyæmia has a sweet, nauseating breath. The rank, unbearable odor of pus from the middle ear tells the tale of the decay of osseous tissue. In scurvy the odor is putrid, in chronic peritonitis musky, in syphilis sweet, in scrofula like stale beer, in intermittent fever like fresh-baked brown bread, in fevers ammoniacal, in hysteria like violets or pineapple. Measles, diphtheria, typhoid fever, epilepsy, phthisis, etc., have characteristic odors.

An Old Medical Work.—Dr. Dodson (*North Carolina Medical Journal*, July 20, 1896) writes as follows: In ancient Egypt the god Thoth was the guide of physicians and left his MSS. in the oldest known book in the world, the Prissi Papyrus. This book, written in the sixteenth century before Christ, contains on one hundred and ten pages the hermetic book upon the medicines of the ancient Egyptians, known also to the Alexandrine Greeks. These pages are supposed to be the revelations from the god Thoth, and with the drugs, prescriptions, weights, and measures are also the pious axioms to be repeated by the physician. He uses these in compounding his drugs. These various incantations smooth his way to the minds of his patients.

Labor.—Dr. Hirst says: "In the earlier stages of excess of expulsive power of the uterus, if the pains be so frequent as to threaten exhaustion, nerve action and muscular power may be lessened by the administration of chloral in fifteen-grain doses every fifteen minutes until three doses have been given. Opium and bromide may also be used. If the patient is irritable, establish mental control. If there is uterine inertia, the majority of cases must be treated in the first stage by inunction, in the second by the forceps. If the inertia is due to weakness or fatigue, quinine, fifteen grains, or stimulants may be given. If there is apathy of the uterine muscle, lukewarm injections of water should be made against the anterior wall of the cervix. Ergot should not be given, as it causes tetanic spasm and contracts the cervix."—*Medical World*, June, 1896.

Consanguineous Marriages.—The results of these marriages have been differently regarded by various authors. Esquirol attributed to them a predisposition to insanity among the descendants. Ménière affirms that in the majority of cases deaf-mutes owe their infirmity to the ties of relationship between their parents. Lucas thinks that these marriages are a cause of degeneration in the human race; that they produce mental dulness, brutality, insanity, impotence, etc. Liebreich states that consanguinity is frequently the cause of pigmentary retinitis among the descendants.

Raynaud ranks consanguinity among the conditions which may produce albinism. Luys seemed to have proved also, says the writer, the injurious influence of consanguineous marriages. On the other hand, says the writer, others have boldly declared themselves in favor of these marriages, and state that they are not at all injurious, that generally they give good results. It is not astonishing then, he says, that in the face of such extreme opinions other authors, such as Lévy, Bouchardat, Voisin, Darwin, Lacassagne, Ballet, and others, should view the question from both sides and affirm that these marriages are productive of both good and evil results, according to whether the contracting parties are exempt from or affected by constitutional diseases. With such a diversity of opinions, continues the writer, it is difficult for physicians to decide when they are consulted by patients in regard to the subject. M. Perrin recently made a study of the question under consideration, and gives his conclusions as follows: First of all, among the numerous affections attributed to marriages of consanguinity, idiocy, insanity, and epilepsy are due generally to heredity, but in a few cases consanguinity of the parents may certainly be the cause. As to convulsions in the young, the cases are so numerous that it is impossible to attribute this affection to the influence of consanguinity. It may have a share in the production of deaf-mutes, but it is not an invariable factor. With regard to affections of the sight, the influence exercised by consanguinity has been ascertained, and in albinism it has been distinctly proved. Concerning sterility, M. Perrin thinks this cannot be attributed to consanguinity alone. He has further shown that certain congenital deformities have been so frequently observed in children whose parents were perfectly healthy that, in these cases, we are forced to admit the theory of consanguinity alone. On the whole, says the writer, we may conclude that if under certain circumstances consanguinity and heredity are two etiological factors which combine in the same family to bring about the same morbid results, it is none the less true that in some cases consanguineous marriages among healthy persons may exercise an unfavorable influence on the children. M. Perrin, says the writer, advises physicians not to dissuade their patients from marriage if there is no diathesis, no hereditary disease, and if they are in good health and have strong constitutions; on the other hand, it is not well to encourage them, he says, because even in the best conditions the children of such marriages have presented irremediable defects. But if the physician discovers the least trace of physical or mental affection, he should exert all his influence to prevent such marriages, for they could only be productive of deplorable results.—*New York Medical Journal*.

The Emergency Ration.—A board of officers has recommended to the secretary of war the following as a suitable emergency ration for the United States army: Hard bread, 16 ounces; bacon, 10 ounces; pea meal, 4 ounces; coffee, roasted and ground, with 4 grains saccharin, 2 ounces, or a half-ounce of tea with 4 grains saccharin; salt, .64 ounces; pepper, .04 ounces; tobacco, half-ounce; making a total weight, with coffee, of 33.18 ounces; or, without tea, 31.68 ounces.

A Living Serre-Fine.—Greek barber surgeons in the Levant use large ants to keep together the edges of cuts. The ant, held with a forceps, opens its mandibles wide, and as soon as it seizes the edges of the wound has its head severed from the body, but retains its grip. People have been seen with wounds healing held together by seven or eight ants' heads. The kind used is a species of big-headed camponotus.

THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP, WITH ESPECIAL REFERENCE TO THE HOFFA-LORENZ OPERATION, WITH AN ILLUSTRATIVE CASE.¹

By ROYAL WHITMAN, M.D., M.R.C.S.,

NEW YORK CITY,

CLINICAL INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS AND CHIEF OF THE ORTHOPÆDIC DIVISION OF THE VANDERBILT CLINIC; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED; ADJUNCT PROFESSOR OF ORTHOPÆDIC SURGERY IN THE NEW YORK POLYCLINIC.

CONGENITAL dislocation of the hip, although not a common disability, is certainly not a rare one, if one may judge from the report of the Hospital for Ruptured and Crippled, in which are recorded fifty-one new cases for the year 1895, although undoubtedly the histories of many of these patients may also be found in the records of other institutions, as may always be assumed of cases of a peculiar or incurable nature.

Although a satisfactory explanation of the exact causes of the displacement is still wanting, the knowledge of the anatomical conditions, until recently in great degree speculative, is now firmly supported by hundreds of observations recorded by Hoffa, Lorenz, and others. An indication at least of an acetabulum is practically always to be found in its proper position, and it is often of nearly normal size and shape. The upper extremity of the dislocated femur is somewhat smaller than normal, the head of the bone is usually flattened from side to side or otherwise distorted; the neck is short, almost invariably depressed to a right-angled relation with the shaft, and may be bent somewhat forward; the ligamentum teres is usually absent after the age of five years; the capsule is hypertrophied and often drawn upward into a somewhat purse-like form.

These changes, which at an early age are in great degree the result of altered function, are progressive in character under the influences of weight, pressure, and attrition on the parts immediately involved, and are accompanied by corresponding effects on the use and ability of the limb and on the posture of the body.

It is evident, then, that whatever is to be done for the relief or cure of the disability must be undertaken at as early a time as is practicable. The only questions can be whether or not the disability is sufficiently serious to warrant the attempt to remove it, and, if so, what means are to be employed toward this end. These questions are by no means settled, if one may judge from the advice that patients accumulate in their journeys from physician to physician and from clinic to clinic.

As the disability is not attended by notable pain, the mothers may be assured that it will be outgrown and that it is of no consequence. Or, if the true nature of the deformity is recognized, it is instinctively compared in the mind of the surgeon with the traumatic dislocation of the adolescent or adult, not only

to the belittling of the importance of a disability that is not accompanied by limitation of motion or pain, but to the exaggerating of the difficulty of effective treatment. It must be understood, then, that the question of treatment is to be considered and decided, not by the present condition of the patient alone, but by the knowledge of what the final effect of the deformity is likely to be; and there is both theoretical and practical proof of the statement that as the anatomical deformity tends to increase, so with age its clinical symptoms will become more evident.

The congenital dislocation of the hip is practically always a dislocation on the dorsum, upward and backward. If the displacement is of both sides the pelvis is suspended by the elongated capsules on femora whose heads are above and behind their normal position.

The effect of the deformity on the gait and appearance of the patient is in brief as follows: As the support of the body is displaced backward the pelvis is tilted forward, and the necessary compensation in the erect posture causes an increased lumbar lordosis and prominent abdomen.

Because of the absence of a firm support for the femoral heads, they are alternately forced upward in walking. This insecurity, increased by the functional weakness of the muscles attached about the neck of the bones and their abnormal separation and displacement, causes the peculiar rolling, waddling gait, so ludicrous, ungraceful, and characteristic that the diagnosis of the affection may often be made at a glance.

When the dislocation is of one side only the waddle is replaced by a limp which is, however, peculiar in its characteristics. As the head of one bone only is displaced upward and backward, the lumbar lordosis is less marked, but the pelvis is twisted; the anterior superior spine of the dislocated side is always in advance of the opposite side and at a lower level (Fig. 1). There is a peculiar telescopic limp, a sudden and exaggerated lunge of the trunk toward the short leg, that has been likened to the motion of descending steps (Fig. 2). The abnormal mobility may cause attrition, and sudden strain upon the weakened joints may set up attacks of traumatic synovitis.

The extent of the secondary changes, the amount of pain, and the increase of restriction of motion will depend in great degree upon the strain to which the weakened part is subjected. It may, I think, be stated that a double congenital dislocation of the hip would make a laborious occupation impossible; fortunately, the great majority of cases occur in females, so that the question is of less importance than it would otherwise be.

It may, then, be confidently predicted of the individual suffering from this disability that the awkward and noticeable waddling gait will continue; that weakness and disability, compared with the normal condition, will be marked; that pain or discomfort in the lumbar region, which is almost always the accompaniment of abnormal lordosis from any cause, will be experienced at times; and that discomfort or pain at the weakened joints may be expected after overexertion.

There is a probability that the disability will in-

¹ Read before the orthopædic section of the New York Academy of Medicine, February 21, 1896.

crease, and there is a very decided possibility that the restriction of motion and repeated inflammations may to a great extent disable the patient in later life.

The same prediction as to slowly increasing limp, weakness and disability, may be made of the one-sided dislocation; not only is the actual shortening increased by the dislocation, but to this may be added the apparent shortening due to the increasing limitation of abduction and tendency toward permanent adduction of the limb.

If these statements can be supported by clinical ex-

FIG. 1.—Congenital Dislocation of the Left Hip, illustrating the twisting of the pelvis and the abnormal lordosis.

FIG. 2.—Front View of the Same Patient, illustrating the inclination of the body, the prominence in the trochanteric region, the comparative atrophy and shortening of the leg.

perience, I think it will be acknowledged that, even did not the weakness, awkwardness, and deformity of the immediate condition warrant interference, the knowledge of the more important disability of later years, not to mention the moral effect of a noticeable deformity, makes the only question one of the probability of the attainment of a cure or relief, and not of the possible difficulties in reaching this end.

In times past such arguments have been sufficiently conclusive to stimulate treatment lasting through years, by the use of braces and even by confinement to bed, and it was only the hopelessness of cure by such efforts that led to the practical abandonment of this method of treatment. Here and there one finds recorded a case successfully treated by apparatus, but even the most favorable report makes no claim that the head of the bone had actually been replaced in a sufficient acetabulum, supposing such to exist.

The object of the splint treatment has been simply, by drawing the head of the bone into the neighborhood of the acetabulum and by removing the strain of functional use, to check for a time the progression of the deformity. This can undoubtedly be done; the more efficient the support and the longer it is used, the greater the palliation, but when the support is removed one may again expect the slow increase of the disability; so that except in selected cases and except for the purpose above stated, this treatment no longer deserves serious comment.

There now seems to be, if not an open acknowledgment, certainly a tacit acceptance of the fact that there can be but one effective treatment of this condition, and that is to replace the head of the bone in its normal position, either in the acetabulum or an enlargement of its rudimentary indication. The credit of this great advance undoubtedly belongs to Hoffa, but the details of the operation in the direction of simplicity and effectiveness have been so essentially modified by Lorenz that it seems necessary to couple his name with that of its originator, and especially since Hoffa has long since abandoned the method of operating that formerly went by his name.

The conception of the treatment is Hoffa's; the operation is that of Lorenz. It seems proper, therefore, in order to avoid confusion, to speak of the treatment as the Hoffa-Lorenz operation.

The delay in accepting and practising the method may be ascribed to the unfortunate functional results that have followed the few reported operations in this country—results that were unsuccessful or only partially successful either because of the inexperience of the operator and the failure to replace the bone in a sufficient acetabulum, or because of the faulty technique and succeeding suppuration and contraction by which the limb was drawn into a distorted position.

On the other hand, the most fortunate operation by this method may be disappointing, if too much is expected as an immediate result. It cannot be hoped, for example, that a perfect joint can be made by placing the deformed femoral head in a more or less artificial acetabulum, nor that muscles whose relations and functions are suddenly changed can balance the body or move the limb through its normal arc.

The operation is distinctly for the future of the patient; it is simply claimed that if the head of the femur may support the body by the secure resistance of an acetabulum in its normal position, compensatory deformity of the body will disappear because the balance has been restored; the shortening will be reduced, insecurity will be replaced by security, and the disability will become gradually less rather than greater, because distortion of the limb and attrition of the bone will be prevented, and the accommodative changes of the future will be toward the normal rather than the abnormal.

Again, as these operations are performed in childhood, when the regenerative and accommodative power is so great as to ensure useful joints even after destructive disease, we can well imagine how much more effective may be the accommodation to a condition free from morbid influences.

So far, then, as the immediate result of an operation is concerned, it may be considered a success if the head of the bone is securely held in the new position, if there be no contractions that distort the limb and a range of motion from complete extension to forty-five degrees of flexion, sufficient to allow the patient to sit with comfort. If these essentials are attained, the patient has made the most important step toward complete recovery.

The following illustrative case is of interest, as this appears to be the first occasion on which a patient has been presented to a medical society in this country as a successful immediate result of this operation.

The child, a girl, four years of age, was admitted to the Hospital for Ruptured and Crippled on August 25, 1895, during my service as substitute. The peculiar limp and projecting abdomen and a lump in the buttock had attracted the mother's attention when the child began to walk. She was taken immediately to a public institution, where the parents were assured that nothing was the matter. Later at another hospital the mother was told that the child was "spoiled at birth." The deformity had become such an eyesore

to the parents that they readily consented to the proposed operation.

The case was one of typical congenital dislocation of the left hip. The great trochanter occupied the usual position behind and above the normal acetabulum, on a level with the anterior superior spine; the lordosis was well marked; there was the usual twisting of the pelvis and atrophy of the leg, which was one inch shorter than its fellow when no weight was borne, and the usual peculiar limp.

On the following morning the Lorenz operation was performed, and, as this has been recently modified somewhat by the author, its main points will be described.

An incision was made just to the outer side of the anterior superior spine, and extended downward and slightly outward for two and one-half inches. The fascia was freely divided and the joint exposed in the interval between the tensor vaginæ femoris and gluteus medius muscles. The capsule was freed and opened,

December 15, 1895. As the parents live far from the hospital, she has been seen at infrequent intervals only, and has had none of the massage, the manipulation, and the special training that have been insisted on by Lorenz as an indispensable part of the treatment, other than that which a busy mother has been able to apply. For this reason the case is of interest as showing a result attained under the ordinary unfavorable conditions.

The head of the bone is securely held in the new acetabulum. The abnormal lordosis has disappeared; the shortening is reduced to about one-fourth of an inch, representing the change in the angle of the neck of the bone; there is no prominence in the region of the trochanter. The child runs about all day without fatigue. There is still a well-marked limp, though of an entirely different character from that observed before the operation, and when the child is under direct instruction it can be much reduced. Contraction has disappeared and there is voluntary motion from full

FIG. 3.—To Illustrate Voluntary Flexion Five Months after Operation.

FIG. 4.—The Weight Supported on the Replaced Femur, illustrating, when contrasted with Fig. 1, the absence of abnormal lordosis.

FIG. 5.—Front View of the Same Patient.

exposing the head of the bone; this was of fairly normal appearance, somewhat like an acorn in shape, with a deep depression on its anterior surface. The neck was as is usual, short and depressed to a right angle with the shaft. The ligamentum teres was absent. The situation of the old acetabulum was found, and it was, rapidly enlarged to a sufficient size. When the upper part of the capsule had been thoroughly divided the head of the bone could be easily replaced.

The capsule was not sutured, the wound was closed except for a small drain, and the limb in a slightly abducted position was placed in a long spica plaster bandage.

The after-history is not eventful. The original bandage remained in position for a month; it was then replaced by a short leather support, which was in turn removed three weeks later, since which time no support has been used. The child began to walk about on the leg at the end of six weeks. Although the importance of after-treatment was recognized, it was not considered best to retain a young child exposed to the dangers of a large hospital, and she was discharged

extension to one hundred degrees of flexion; abduction, adduction, and rotation are about three-fourths of normal, which means that for all practical purposes motion is perfect (Figs. 3, 4, 5).

According to Lorenz's experience this case may be classed as one of the best results, since he considers a very much more limited range of motion, from fifteen to forty-five degrees, a good result. As to the limp, which depends on insecurity, it may be expected to grow less with functional use, because it is the insecurity of muscular weakness, not the insecurity of non-support. For the immediate result, the better the motion the greater the limp; in fact, according to Lorenz, the firm ankylosis that might follow suppuration gives a better immediate result, provided there is no distortion of the leg. In from one to two years the limp may become imperceptible, much naturally depending on the training and after-treatment.

So far as the operation is concerned, from my own experience and from my observation of those performed by others, the following points deserve attention:

The operation is somewhat difficult, since its field is

deep and cannot be easily exposed to view. The neck of the femur is short and held tightly against the pelvis by the hypertrophied capsule. The operation should be as rapid as possible, and this rapidity may be aided by an accurate knowledge of the normal position of the acetabulum and a clear conception of the size and shape to which the rudimentary depression is to be enlarged, and it must be remembered that this is to be large and deep. The capsule should be freed, incised, and cut through, particularly at its upper attachment, as it is at this point that the resistance to reposition is most marked. In young children the obstacles to reposition will be found to be almost entirely in the capsule. In older subjects the preliminary extension by heavy weights or the extension by the screw machine at the time of operation may be necessary. In exceptional cases the head of the bone may be distorted so that shaping may be necessary.

It is evident that although the dislocation may be successfully reduced, the necessity for long-continued and careful after-treatment is not thereby removed; but it is care applied to a useful, growing limb, securely in place, rather than the same amount of treatment devoted to holding the limb approximately in normal position, as when mechanical means only are applied.

It is probable that the only other method of treatment likely to be extensively used in the future is the attempt to replace the dislocation by manipulation without open operation, as advocated by Paci; but this method must have a much more limited scope than is claimed by its author, for if its object is to actually replace the dislocation, it is not likely to be successful except in young children, because the acetabulum is not of sufficient size to contain the bone, and because the opening through the elongated capsule is impossible, not to mention the other difficulties in the resistance of muscles and ligaments, which are sufficiently familiar to those who have attempted the open operation.

Lorenz's argument is particularly conclusive on this point, as he has performed the manipulation of Paci, and then by the open method examined the relation of the parts and again laid bare the capsule and attempted reposition by this method—but never with success. He insists that the "fourth movement" of Paci will inevitably dislocate the head of the bone forward if it comes into the neighborhood of the acetabulum, and that it is because of this forward dislocation that the favorable results are obtained by this method.

Lorenz also asserts that the only effective method for the actual and immediate reduction of a dislocation by such means must be by traction, flexion, and extreme abduction; direct pressure downward on the trochanter and then toward the median line, while the leg is rotated slightly inward. He has further perfected the method and it will be described by him at the May meeting of the Orthopædic Association. As neither Lorenz nor Hoffa advise open operation before the age of two years, it would seem that the attempted reposition would be indicated in those rare instances in which one has the opportunity to apply treatment at this early period; and if, as is no doubt the case, the anterior dislocation is so much less disabling than the posterior, it would seem that the method of Paci might be carried out simply with this aim in view, if it were impossible to replace the head of the bone in its acetabulum, or when the open method had been refused or was considered to be impracticable.

Were it not for the continual evidence of mistakes in diagnosis that cases afford, one would suppose that the presence of the dislocation must be self-evident. The diagnosis can offer no difficulty in any

but very exceptional cases. It is characterized by an habitual limp or waddle not accompanied by the pain of joint disease or the helplessness of paralysis (the affection which I find most often made to explain the symptoms): a shortening of the leg, explained by the elevation of the trochanter on the affected side or on both sides when compared with Nélaton's line; finally, when the limb is flexed and adducted to its extreme limit, the neck and rounded head of the bone can be plainly felt, beyond and above the trochanter. Thus it may be distinguished from the rare cases of depression of the neck of the femur, which in young children may be due to rachitis, and from the dislocation the result of destruction of the head of the bone, as in acute epiphysitis of infancy, of which no history can be obtained.

Fortunately at the present time, thanks to the work of our European colleagues, Hoffa and Lorenz and Paci, the congenital dislocation of the hip is no longer a hopeless disability. The simplicity and the reasonableness of the operative method have always been self-evident, and now that its feasibility has been so decisively proved it would seem that the time had come for more decided effort to relieve the sufferers from this deformity.

RUDIMENTARY ORGANS.¹

BY CORA H. FLAGG, M.D.,

BOSTON, MASS.

In all of the higher animals we find a large number of structures which are either absolutely useless or of such slight service as to bear little or no relation to the existing life or wants of the animal.

Those parts which are absolutely functionless are, strictly speaking, rudiments—though it is hard, in many cases, to make a distinction between them and those that have so far degenerated as to be of slight or doubtful value.

A very liberal interpretation of the subject would make it include those structures which were formerly of greater physiological importance than at present, or parts that may be in a state of transition, and even those that are merely pathological in their significance.

All rudiments are characterized by their great variability, either in size, form, sex, time of occurrence, or their entire suppression. They are often a source of decided disadvantage and even of danger to life, as in the case of the vermiform appendix.

To comparative anatomy and embryology we owe much for the elucidation of this subject. Comparative anatomy shows us that all vertebrates are constructed on the same plan: so, finding the same parts which are rudimentary in higher animals well developed and highly functional in the lower animals justifies the conclusion that these parts in the higher animals are now in a degenerate and functionless condition, but that they once had an important function in ancestral forms.

The human embryo shows successively and progressively during the course of its development the ancestral forms through which man has passed in the ascent from the simple to the complex organization. To briefly illustrate: The embryo of man has at an early period gills much like a fish, with ramification of blood-vessels in true fish type. These are found in the embryos of all existing vertebrates, together with other structural peculiarities which would result in the transformation of an aquatic into a terrestrial animal. The heart is at first a simple chamber, like that in the

¹A prize essay, College Physicians and Surgeons, Boston, Mass., session 1895-96.

worms; the backbone is prolonged into a tail, which extends beyond the extremities; the great toe is opposable like the thumbs. Three months before birth the whole body, except soles and palms, is covered with a thick coat of soft woolly hair. In short, the human embryo, during its development, recapitulates the history of the evolution of all its ancestral forms. In consequence of this, we have found in the embryo more than three hundred rudimentary parts or characters, most of which disappear in the economy of growth, but many are retained in the adult form. Of these I shall consider only those of general interest, and that necessarily in a superficial manner.

As to the part played by a gradual evolution of the environment, the laws of natural selection, disuse, economy of growth, or the combined effects of enlargement from increased use, suppression, and change of function, I cannot touch upon at all. This phase of the subject has been most extensively and satisfactorily worked out. Suffice it to say that rudimentary organs have furnished a most perplexing problem to those whose interest or condition of mind lead them to seek a teleological explanation of man's origin. Viewed only in the light of evolution has their meaning been made clear.

Let us begin with that most obnoxious of all rudiments, the human tail. Has man a rudimentary tail? In answering this question we must bear in mind that the definition of a tail in human anatomy must be in strict accord with that of comparative anatomy, which is, "that so much of the vertebral column as is posterior to that which attaches to the pelvic girdle is caudal." At an early stage in the development of the human embryo there is, as we have already said, in direct continuity with the axial skeleton, a free, pointed appendage, projecting beyond the extremities, and having an unmistakable resemblance to the tail of a lower animal. During the course of development this becomes shorter and shorter, is slowly taken into the trunk, and persists in the adult form of both man and apes as the *os coccyx*. As is the case with all vestiges, it is extremely variable; being made up usually of four vertebræ, it is found sometimes in the male composed of five, while in the female the number varies from three to six. That it is a true rudiment is shown by this variability in number, its incomplete development at birth, together with the fact that there is a whole series of degenerate caudal muscles attached to it. This is also a direct proof that it was at one time an external and functional tail. Although functionless now as a tail, the *coccyx* has some use in supporting internal parts.

The skeletal system furnishes many points of interest, on account of the assumption of the upright position by man. In consequence of this, the sternal portion of the thorax has shortened and the sternal ribs have diminished in number and size, because the chief support of the viscera is no longer in the ventral but in the caudal direction. We find, consequently, a compensatory widening of the pelvis, especially pronounced in woman, furnishing additional support in child bearing.

We must consider the eleventh and twelfth ribs—and a thirteenth rib is not a very rare occurrence—as rudimentary in nature. They have lost their sternal attachment. It is found that their chief use is in giving support to the serratus posticus inferior and a portion of the latissimus dorsi muscles; but it must be noted that the former muscle is unmistakably rudimentary, while that part of the latissimus dorsi attached to the ribs is very insignificant compared with the rest of the muscle.

The large transverse processes of the lumbar vertebræ must be considered as vestiges of ribs. In fact, they are ribs at one period in the embryo. The first

pair of ribs also shows signs of beginning degeneration.

From these facts we see that the vertebral column was evidently furnished with a greater number of ribs than at present.

The slender and variable styloid process of the temporal bone is clearly a rudiment, a left-over or made-over structure from the gill stage.

Probably the most harmless rudiment we possess is the pisiform bone of the wrist. As all mammals are constructed on the common plan of five digits, and as careful research shows this vestige to be the carpal bone of a long-vanished sixth finger, we shall have to go back at least to the amphibia to account for its origin.

Numerous foramina are found in certain bones, occasionally in those of civilized man, more commonly in ancient remains and the lowest races. We need mention but one that always occurs, the canal in the posterior aspect of the petrous portion of the temporal bone, the aquæductus vestibuli. It has been fully investigated and proves to be one of the most ancient and interesting of relics. It is the rudiment of a structure which primitively connected the inner ear directly with the external world, and opened on the dorsal aspect of the head. This is evidenced by the following facts: In the embryos of all vertebrates the development of the auditory vesicle begins by the formation of a patch of exoderm cells. This patch soon becomes invaginated and forms a pit, to the inner side of which the auditory nerve becomes closely applied. As this pit sinks deeper and deeper into the connective tissue, its mouth narrows and soon becomes closed in all higher vertebrates. The ear vesicle gradually moves still farther from the surface, yet remains connected with it by an elongated duct, either opening on the dorsal aspect of the head, as in elasmobranchs, or ending in a blind pocket. In the higher vertebrates the ear vesicle undergoes most complicated changes, which have been confined, however, wholly to its lower end, leaving this primitive dorsal external auditory canal unused. It still persists in man as a canal leading from the vestibule of the complex inner ear and opening on the top of the petrous bone. Some anatomists tell us that it still contains a tubular prolongation of the lining membrane of the vestibule, which ends in a cul-de-sac between the layers of the dura mater. To sum up: The aquæductus vestibuli is all that is left of the primitive ear tube through which the remote ancestors of man, the early sharks, heard.

It is said that hardly a human subject has been examined which has not shown some variation in the muscular system. In fact, in no other system do we find so many variations. On account of the degeneration of the tail, we have a whole series of muscles, which in tailed animals are strongly developed, for moving it. On the ventral side of the *coccyx* are the vestiges of the *coccygeus* muscle, being in the lower animals the adductor *coccygeus* or tail-wagging muscle. The *curvator coccygeus* corresponds with the depressor *cauda* of the tailed animals. The rudimentary character of the extensor and levator *coccygei* is indicated by their extremely small size and by the fact that they may be wholly or partially replaced by fibrous tissue, or may be entirely wanting. Their vestigial character is even more pronounced in the anthropoids than in man.

An interesting series of muscles is the *panniculi* or skin muscles—so called because they have their points of origin and insertion in the skin. They are well developed in many of the lower animals, in which they spread like a mantle over the back, head, neck, and flanks. They play an important part in raising the scales and feathers of reptiles and birds. In some

mammals they act as a protection against injury to the skin, as is seen in the strong twitching by which a horse or ox shakes off an insect. In man and apes only a feeble trace of this class of muscles is found, such as the *platysma myoides* in the cervical region, the muscles of the external ear, and those of the scalp.

The whole of the external shell of the ear in man is merely a rudiment, having no function whatever in its present condition. Its various folds and prominences in man are represented in the lower animals by muscles which are used for opening and closing or widening and narrowing the external auditory passage. While those three rudimentary extrinsic muscles—the *attollens*, *attrahens*, and *retrahens*—are large and functional in moving the ears of most of the lower mammals upward, forward, and backward, they are outside the control of the will in us, making the ear practically immovable. It has been said that the resting position has had much to do with crumpling the pinna, but to this must be added the effects of disuse through greater freedom of motion of the head and greater brain development. Excepting the primates, mammals determine direction of sound by exclusion—they move the ear until a position is found where the sound is loudest. In our complex brain the terminals of the auditory nerve have so specialized as to be capable of perceiving quality of sound in different relations to the individual. This, plus the capacity for correlating past experiences of sound, enables us to detect immediately its direction, and we have no further need of an external ear with a set of muscles to move it. Elaborate experiments have been made to prove that the crumpled condition of our ear deflects rather than concentrates sound vibrations. In the little blunt point projecting from the infolding margin of the helix we see the last relic of the pointed ears of our ancestors, which fact is emphasized by our finding it in the human embryo (before that stage when the helix rolls in) projecting upward, as is normal in the ears of lower mammals.

The *subclavius* in man is very small and insignificant, often only a band of fibrous tissue and as often absent. It may have a little use to aid in steadying the clavicle during movements of the arm, for we find an analogous muscle in birds, which is large and strong, raising the wing in flying.

The *pyramidalis* has the rudimentary character of variability. It is very insignificant, often wanting on one or both sides. It is the remnant of a powerful muscle, which in the marsupialia greatly strengthens the abdominal walls and supports the pouch.

The *levator claviculæ*, *ischio-pubic*, *musculus sternalis*, *gluteus quartus* are interesting rudiments, which we need not treat in detail.

The *palmaris* in the forearm and the *plantaris* in the leg are good examples of degenerates. The former is still slightly functional in aiding to "make a fist." Formerly it extended through the palmar fascia to the phalanges, acting as a strong flexor of the fingers. Now it reaches only to the palmar fascia. The *plantaris* is a true rudiment. While it formerly extended through the palmar fascia of the foot to flex the toes, it now does not even reach the fascia, but has shifted back to the *os calcis*, and is frequently absent. This muscle is largely developed in tree-climbing animals.

The assumption of the upright position has had much to do with this great variation in the muscular system. It caused that massive development of the *gluteus maximus* and *gastrocnemius* which must necessarily have thrown out of balance the nicety of relations of other sets of muscles. The changing of the foot from a prehensile to a supporting and walking organ brings into existence rudimental conditions of muscles. Professor Wood, of London, from examination of a large number of cases, finds that anomalies in muscles of the limbs are more numerous than else-

where. And in the arm he finds that there are two hundred and ninety-two variations as against one hundred and nineteen in the leg, owing, no doubt, to complexity of movement in serving a highly developed brain. Osborn says that "in the muscular system we find organs so far on the downward grade that they are mere pensioners on the body, drawing pay—that is, nutrition—for past honorable services without performing any corresponding work."

Although man is the least hairy of all the primates, a careful examination of the skin shows that hair follicles are to be found over its whole surface, in some regions, as the head, axilla, pubes, being strongly developed, while in other parts it is a fine, soft down. In males these downy hairs are often well developed on the breast, neck, abdomen, and limbs. These facts lead to the conclusion that primitive man was far more hairy than at present. To go back further, we can even see in the rudimentary condition of the hair of man traces of his descent from the lower animals. Hair appears on the embryo of homo at about the thirteenth week of intra-uterine life. The very first is seen about the eyebrows and mouth, the same parts where the "whiskers" or tactile hairs of lower animals are found. At about the sixth month the whole body, except the palms and soles, is covered with a soft, thick hair, called the "*lanugo*." This soon disappears and gives place to the developing buds of the permanent hair follicles.

In the mamma we have an organ, functional in one sex, rudimentary in the other. It is clearly indicated that some remote ancestor of the vertebrates must have been hermaphrodite, which indication is strongly accentuated by this embryological fact: at a very early period in foetal life both male and female glands occur in the same individual. In a short time one gland disappears. Which gland shall disappear and which shall persist, is determined by conditions which are not as yet fully understood.

It is significant in this connection that every human being at one period of its existence is double-sexed or hermaphrodite.

During the past few years an immense number of cases have been recorded of the occurrence of more than one pair of mammae. These instances of polymasty occur equally in both sexes, and may be regarded as a return to a primitive condition, where many glands were developed and many young were brought forth at one birth. There has been a large amount of research on this subject and numerous facts have been collected, which go to show that the male mammae are not merely inherited from the female but are true vestiges derived from hermaphrodite ancestors. Occasionally they are functional in the male. There are data which point toward degeneracy of the female mammae, one cause of which may be found in present modes of dress. A physician of large professional experience and observation says that degenerate malformation of the nipple is quite common, and it may be well to investigate how far the pressure of the corset is a cause of this.

The lowest races of men, as well as the apes, still retain the wisdom tooth as the largest in the series, while in civilized man it is clearly a rudiment, having many variable characteristics. It is late in its development, sometimes not appearing at all. Instead of a molar with four cusps, it is often but a stump with coalesced roots. It is the earliest to decay. The habitual eating of soft food, which the use of fire permits, does away with the necessity for heavy jaws for the attachment of powerful masticating muscles, and is the initial factor which tended to weaken and shorten the jaws, crowding out the wisdom tooth.

In certain glands of the axillary and anal regions the secretions have a penetrating odor, of which we are

not able to discover any use in man. But it is well known what an important part they play in mammals on account of their odorous secretions.

The nervous system is conservative in preserving antiquated structures. Still persisting in this system we have the last traces of the invertebrate descent of man in the mysterious pineal gland, the rudiment whose history has most recently been cleared up. Speculations concerning its nature began as far back as the time of the Greek philosophers, by whom it was thought to be the seat of the soul. It is a small, reddish, cone-shaped body, about the size of a cherry stone, which in man and the other mammals is pushed away from the surface of the brain by the growth of the cerebrum, until it has come to occupy a depression between the corpora quadrigemina. Its base is divided into two stalks, which are intimately blended with the optic thalami. In vertebrates, lower than mammals, this organ lies just under the top of the skull, at the parietal foramen. The pineal gland is now known to arise during the development of all vertebrates, and to have undergone degeneration in proportion as the skull became more and more solid. In the lower vertebrates—the amphibia and reptilia—the pineal body is found to be divided into two parts, one part still connected with the brain, while the other, made into a bladder-shaped structure, is closely connected with the first part. An English and a German scientist, both working independently on the brains of certain reptiles, discovered that the pineal gland in these animals was a true optic lobe, and that the bladder-shaped appendage was the rudiment of an unpaired, highly-developed median eye. While in all vertebrates we find this pineal optic lobe, in only the lowest vertebrates do we find the rudimentary pineal eye connected with it. Yet we do find the eye in the embryos of animals still a little higher up the scale. All that persists in man and the higher vertebrates is this pineal optic lobe, all trace of its associated eye having long disappeared. In the *Hatteria punctata*, the sole survivor of an extinct species of beak-mouthed lizard, found in Australia, we find a well-developed pineal eye on the top of the head, covered with a transparent scale, which acts as a cornea. In this animal there is a nerve connection between the eye and the pineal gland. But in even this low form its degeneration is begun, as is shown by the deposition of a mass of pigment cells under the transparent scale, which renders the eye functionless. In *Varanus*, a more modern type of lizard in which the pineal eye is found, there are no pigment cells to obstruct sight, but degeneration is shown here by the absence of the nerve connecting the pineal eye and the pineal optic lobe. It is interesting to note that in many animals the skin, connective tissue, and dural tissues over the parietal foramen remain uncolored; sometimes they are so clear and transparent that they might be considered a kind of cornea. In considering the intimate relationship between birds and reptiles, a Russian zoologist has discovered in the embryos of certain birds a brow spot, also a transparent scale like that of the now living lizards above mentioned, which in their structure point to the last trace of a pineal eye. Careful examination shows this eye, whether found in the embryo or in the adult form of still lower vertebrates, to be of the type of an invertebrate eye. To sum up briefly: The pineal eye is never functional in vertebrates when found. The only vestige left of it in higher vertebrates is the optic lobe or pineal gland, which must be considered as an heritage from the seeing apparatus of an invertebrate ancestor.

We find another rudimentary organ in the pituitary body of the brain, which, although not yet ontologically solved, bids fair to throw more light on our remote ancestry. The *lobus olfactorius*, although func-

tional, is in a degenerate condition. There can be no doubt that we inherit the sense of smell in an enfeebled condition from our early ancestors, in whom it was of very great service in guiding them to food and warning them of danger.

The *calamus scriptorius* is as yet an unreadable rudiment.

The eye presents an interesting rudiment in the little fold of the conjunctiva which lies at its inner angle, and is known as the *plica semilunaris*. This membrane corresponds to the third eyelid or nictitating membrane of the lower animals. In birds, reptiles, and some amphibians, in whom the upper and lower lids are nearly immovable, it is highly developed and can be drawn wholly across the eye by means of a special muscular apparatus. The use of the nictitating membrane in the lower animals is to maintain the healthy condition of the eye by removing foreign matter which has escaped the eyelids. What clearly demonstrates this function is the inverse relation which always exists between the development of this body and the facility with which the animal can rub the eye with the anterior limb. Thus, in the horse and ox it is well developed, while in the dog, which may use its paw to some extent when it is required to brush its eye, it is smaller. In the cat it is still less, while in man and the monkeys, whose hands are perfect, it is reduced to a very small rudiment. It serves also to cover the eye in the lower animals, as well as to keep it clean; but in man that function is wholly performed by the lids. Although in man and the higher apes this membrane has undergone extreme degeneration, yet in some of the more primitive races it frequently encloses a cartilaginous support.

The function of the suprarenal capsules is still unknown. We are justified in classing them among retrogressive organs, from the fact of their larger size in the embryo than in the adult.

In many places where canals open on a free surface the orifices are usually surrounded with glands and a collection of tissue of the adenoid variety. The tonsils are an example of this, occurring in the throat, marking the inner border of the gill-slit orifices. They are among the dangerous rudiments in man. There is a third tonsil in the vault of the pharynx; although not associated with the gill slits, yet it is a curious fact that it is situated at the pharyngeal orifice of a duct which in the embryo traverses the floor of the pituitary fossa and opens into the roof of the pharynx. This tonsil is identical in structure with the tonsils of the fauces. As is well known, adenoid tissue has an inherent tendency at slight irritation to increased activity of its cellular elements, thus enlarging the mass. This enlargement, especially of the pharyngeal tonsil, is the source of much trouble in childhood.

Between the true and false vocal cords there is on each side of the larynx a diverticulum, known as the sinus of Morgagni. This invagination is directed outward, sometimes upward. In man these Morgagnian pouches are variable and, so far as we know, functionless. But we have no difficulty in recognizing in them the homologues of the vocal sacs of the monkeys. In them they can be filled with air from the lungs, and when so filled are of immense size. Their only conceivable function is to act as resonators when the animal howls. From these facts we might be led to investigate the probability of these sinuses playing a part in influencing the quality of the singing voice in man.

Nothing is definitely known of the function of the thyroid gland. The manner in which it originates justifies us in classing it as a vestigial organ. There are strong evidences of its having undergone a change in function, which, so far as we can say, appears to have an important relation to the central nervous sys-

tem, since its removal is apt to give rise to idiocy, muscular twitchings, epileptoid movements, disturbances of deglutition and respiration. Its probable function is to form a secretion or remove some waste from the blood that would injure the nervous system.

The thymus gland is still more difficult to understand. It is large in the embryo. At the end of the second year it begins to degenerate. In old people there are still epithelial, lymphoidal, and fatty vestiges of it always present. The fact that it has its greatest development in the lower fishes may enable us to determine its function in them, thus giving us a clew to its use in homo.

The vermiform appendix is probably the most dangerous rudiment that we possess. Let us consider a few facts that have been collected concerning it. It is a feebly developed organ, which is attached to the short cæcum. Its average length in man is four inches. It is strongly developed in the embryo—its length, in proportion to the large intestine, being one to ten, while in the adult this proportion is one to twenty. Ribbert's investigations prove that in a large number of cases it is occluded. His tables show further that this occlusion increases with the age of the subject examined. He has made another table, which proves that occlusion increases as the length decreases. The presence of this rudiment points to the conclusion that the total length of the great intestine, as well as of the body cavity, was formerly greater than now. The great variation in form and size of the cæcum supports this view. The cæcum has a great length in the lower, vegetable-feeding animals. In the marsupial koala it is more than three times as long as the whole body. It is now thought that, on account of changes in diet and habits, the cæcum in man has become much shortened, the vermiform appendix being left as a rudiment of this shrunken part. As is true of all rudiments, it is occasionally absent in man. In looking over the great amount of research that has been made on this rudiment alone, one realizes that in a short paper like this no attention adequate to its importance can be given to it.

Although I stop here in the enumeration of man's rudimentary organs, I have by no means exhausted the list. We might begin to think that man is a sort of Nature's patchwork, were we not certain that every modification of structure is the direct result of that grand, immutable law of the universe, whose working raises the simple into the more complex, develops force diffused into force more concentrated, and that this law is as well shown in the evolution of complex worlds from simple nebulous matter as in the evolution of psychic man from simple forms of life.

374 NEWBURY STREET.

Indications for Curettage.—1. All those cases of persistent leucorrhœa with tender and subinvolved uterus. 2. For dysmenorrhœa in young girls and maiden ladies who, in spite of internal remedies, must spend two or three days out of each month in bed, and in whom an undeveloped and oftentimes flexed uterus is found. 3. For barrenness, when the fault is plainly with the woman, and no tangible cause other than poorly developed uterus exists for failure to conceive. 4. In all cases of menorrhagia, whether from fibroids, polypi, or other neoplasms, especially in the menorrhagia occurring at "the change of life," and which is not amenable to other treatment. 5. In all septic diseases of the uterus or its appendages, whether following accouchement, abortion, operations, or gonorrhœa, whether the inflammation be acute or chronic, curettage is indicated, and the earlier the better.—DR. LANCASTER, *Virginia Medical Semi-Monthly*, May 22, 1896, p. 97.

SYMPHYSEOTOMY.

By EDWARD A. AYERS, M.D.,

PROFESSOR OF OBSTETRICS, NEW YORK POLYCLINIC.

GENTLEMEN: Until September 30, 1892, when your distinguished townsman, Prof. Charles Jewett, did a symphyseotomy, but three such operations had been performed in this country, none of which had been reported. To-day our records show some eighty-five and more cases recorded. Over four hundred cases have been reported by Zinke, including all countries. Outside of Italy and France, the operation was as little used in other European countries previous to 1892 as in America. And as in America, so it has been taken up by most of the nations of Europe since that time. Every obstetrician is therefore deeply interested in having its proper place clearly defined.

Scope of the Operation.—The scope of the operation must depend upon the skill required to perform it, the essential mortality that belongs to it, the mortality depending upon the enforced though undesirable conditions under which it must be performed, and their comparison with those of its alternatives—version, induced labor, craniotomy, and Cæsarean section; and upon the after-disabilities to the mother and the mortality of infants delivered by it. It further depends upon the degrees of pelvic contractions, the dimensions of the foetal heads, and the increase of pelvic space obtaining after pubic separation.

Comparative Mortality.—Internal podalic version in cases of contracted pelvis will sometimes secure delivery of a living child when, if it were not employed, an operation with the knife would be necessitated. The tendency of physicians not thoroughly trained in abdominal and pelvic mensuration is to exaggerate the difficulties at times and leap to an operative delivery that is not necessary. In such cases version is conservative. But the most skilled examiner finds it much more difficult to foretell that version will deliver than that symphyseotomy will do so.

It were far better not to undertake a version and fail to deliver, as it only adds to the difficulties by getting the child in the most awkward position for either craniotomy or symphyseotomy.

In the last two years I have done two basiotrypsies, and, through my hospital staff, delivered a foetal head that had been left in the uterus with the body torn away. All three were cases of impossible delivery by version. Basiotrypsy is an easy operation if one has a trephine, but this instrument is in very few offices.

Maternal mortality through version, from exhaustion, rupture of the uterus, or infection, averages from one-half to two per cent. The mortality to the foetus is from ten to twenty-five per cent.

Induced Labor.—The mortality from induced labor is for the mother from one to three per cent. The mortality for the infant in the first six months is from seventy-five to ninety per cent. These figures for infant mortality in prematurity seem large, but the more I have investigated the subject the larger have the figures grown. We must bear in mind that not all this mortality belongs to prematurity. Walcott gives in a recent paper the infant mortality from all causes as thirty per cent. in Bavaria, 20.3 per cent. in Holland, 16.6 per cent. in France, 16.3 per cent. in Massachusetts, and twenty-six per cent. in Boston. The incubator and improved infant feeding have not yet brought premature infant raising to a satisfactory accomplishment. As an alternative to symphyseotomy induced labor loses probably one-half its utility through that percentage of cases not being recognized in time for its performance.

Craniotomy.—There is a very wide variation in the

¹ Read before the Brooklyn Medical Society, April 17, 1896.

mortality of craniotomy. Done early and without damaging effort with the forceps, it is quite a safe operation, unless there is great contraction of the pelvis. Its total mortality is in the neighborhood of fifteen per cent. Done early and with skill, its mortality is from one to two per cent. For the child of course it is one-hundred per cent.

Cæsarean Section.—The best per cent. obtained for Cæsarean section is eight.

The average general mortality is between twenty-five and thirty per cent. For the Porro operation it is nearly thirty-eight per cent. For the infants it is 22.4 per cent. There is little need of so great a mortality for infants, the per cent. being due to some extent to operations after the infant was dead. In others it has been due to the present method of first constricting the uterus before opening it and removing the child. The essential mortality for infants should not be more than in normal labor, if the operation is begun early. The mortality for the mothers will always be high, no matter how great future efforts will be to lessen its dangers. It will always be the operation last selected. I state with positive assurance that the newer operation, symphyseotomy, is sure to have first consideration from this time on.

Symphyseotomy.—The general mortality for symphyseotomy in this country, where all but three cases were done during the antiseptic period, is about nine per cent. Following the admirable tabulated records of over four hundred symphyseotomies, covering all countries, published by Zinke and Harris, I have made a table of only those cases occurring since 1886, when antiseptic surgery was well established and in which the patients had not been in labor longer than twenty-four hours.

This leaves out a number of cases which were successfully operated upon after being longer in labor, but impartiality demands some such definite limit for classification.

SUMMARY OF TABULATED CASES.

Total number of cases, ...	111
Total number of maternal deaths, ...	6
Total number of children born, ...	112
Total number of children died, ...	16
Average number of hours in labor, ...	16

Of the six maternal deaths, Case 78 in Zinke's Table had "septicæmia when admitted to the hospital."

Case 176, Zinke's table, died from septic peritonitis, a condition that was believed to have originated before the operation.

Case 174, Zinke's table, had a periosteal pelvic fibroma, rupture of the vaginal wall, phlegmasia in the left leg, and died from an embolus in the pulmonary artery.

Case 19, Harris' table, died from pneumonia and intestinal paresis from impacted feces.

Case 74, Harris' table, died from septic peritonitis.

Case 6, not yet reported, my own, died over a month after operation from sloughing of large cicatrix in the vagina and from pneumonia.

This table therefore gives a mortality of five per cent. Of these six deaths the first was septic before entering the hospital, the second was believed to be infected before being operated upon, the third, with a periosteal pelvic fibroma, should be counted as a symphyseotomy death, although it was a mistake to select this operation. The fourth case, operated upon by Dr. Davis, of Philadelphia, did not die from symphyseotomy at all. The fifth case, done in a moribund condition, cannot be fairly said to touch the question of the "essential" mortality. The sixth case, my own,

did not have any joint trouble, as will be seen in my report, about to be given.

It is therefore no exaggeration to say that the essential mortality of symphyseotomy is not much over one per cent. I believe the operation is slightly more dangerous than induced labor. I should say it is one per cent. greater risk. On the other hand, the risk for the child by induced labor is fully three hundred per cent. greater: that is to say, a mortality of from seventy-five to eighty per cent. as against twenty to twenty-eight per cent. by symphyseotomy.

As regards the rate of mortality, symphyseotomy takes precedence over Cæsarean section and craniotomy, and is practically on a par with induced labor, but with much superior results in infant-life saving.

Mensural Limitations.—In a separation of two and one-half inches, which is, or should be the limit of diastasis, a gain of half an inch is secured in the diameter of the conjugata vera. The average biparietal diameter of infants at birth is three and four-fifth inches. That of the occipito-bregmatic diameter is the same, so that we have a circle of this size representing the smallest cylinder the foetal head can offer for passage through the pelvis. There is a reduction of about a quarter of an inch in this cylinder by moulding. Three-quarters of an inch to an inch then is gained in space by moulding, pubic separation of two and a half inches, and forceps compression. On the single basis of inches we would say that symphyseotomy should not be undertaken with a conjugata vera of less than three inches. But the elements of variation here are numerous. The pubic bones have been separated by Caruso three and two-fifth and three and three-fifth inches without evil.

The foetal head may be so small that delivery could be accomplished by operation in a conjugata vera of two and one-half inches. Again, the biparietal diameter may be too great for delivery in an almost average conjugate diameter. My third case, of twin renown, had a conjugata vera of four inches, but with a narrowed internal transverse diameter, and both infants measured at birth four and one-half inches in the biparietal diameters.

Practically the most important and difficult factor in leading to a proper selection of cases is the individual doctor's skill in physical diagnosis. I beg leave to call your attention to a new obstetrical history chart which will shortly be published, the aim of which is the development of skill in diagnosis and prognosis in all matters pertaining to an approaching labor.

Methods of Operating.—Three ways of performing symphyseotomy are now recognized: Morisani's, Pinard's, and the one which I recently brought forward at the Academy of Medicine in New York.

Morisani's method of cutting down to the upper border of the pubis, then passing a curved Galbiati knife down behind the joint and cutting from the base up and out, is not popular in this country, as it should not be, being both anatomically and surgically objectionable. Pinard's operation, which consists of cutting down upon the face of the symphysis through the soft tissues and exposing the joint, is a great improvement over Morisani's. The chief objection to it lies in the cutting through the vessels of the clitoris, causing much hemorrhage, and in unnecessarily exposing the joint.

I have operated five times in the last eighteen months by a new method which I described in a paper before the obstetrical section of the Academy of Medicine in January. This paper appeared in the May number of *The Polyclinic Medical and Surgical Review*.

Following are the brief essential points in the operation:

1. Secure full dilatation of the cervix, if possible without risk to the child, before cutting the symphysis.
2. Make the initial incision a little above the subpubic arch and under the elevated clitoris.
3. Have the urethra and bladder held to one side with a small male sound.
4. Introduce the left index finger within the vagina against the posterior ridge of the joint up to the top.
5. Pass a narrow tenotomy knife with the point close to the joint up to within a half inch of the top, and under the overlying soft tissues, cutting the middle portion of the joint.
6. Substitute a probe-pointed bistoury and meet the left index finger with the probe over the top of the joint, and work the blade through the joint downward until separation is felt by the posterior finger.
7. Have an assistant press the mouth of the wound and the tissues lying over the joint with a small piece of gauze.
8. Deliver with the forceps, if possible, and refrain from suprapubic pressure, aiming to deliver the head through the cervix without drawing it down below the symphysis.
9. Hold the bladder well to one side while pressing the pubic bones together.
10. Pass a small strip of gauze into the prepubic wound and another against the cervix after irrigating, leaving both pieces exposed for easy removal, having refrained from stitching cervix or perineum.
11. Dress the vulva with gauze and strap the joint with adhesive strips.
12. Remove all the gauze in thirty-six hours and irrigate the vulva and vagina twice a day, keeping the vulva carefully dressed between times.
13. Attend to catheterization in person.

Following is a report of my fifth case, not hitherto published.

Mrs. K. L.—, aged 29, Irish: one previous pregnancy, four years ago; she was in labor one week, and was attended by a physician who made several visits, then by a midwife, and was finally delivered by the latter of a full-term, stillborn child.

Examination.—She was admitted to the Mothers' and Babies' Hospital February 14, 1896; weight, 110 pounds; last menstruation, May, 1895. Abdominal wall flaccid, prominent in right upper quadrant; iliac crests, 10½ inches; anterior superior spines, 10¾ inches; external conjugate, 7 inches; trochanters, 11 inches; fundus 2 inches from the ensiform; uterus flaccid, thin; amniotic fluid moderate; fœtus movable; head at inlet; fœtus highest in right upper quadrant; back in middle, left side; extremities felt in right upper quadrant; fœtal heart heard in left lower quadrant; fœtal pulse, 112; fœtal movements felt most by the mother in the middle upper portion, head resting in the inlet and movable; head medium.

Vagina remarkably misshapen; a longitudinal cicatrix extended from the posterior part of the cervix to within two inches of the posterior commissure, forming a small, wire-like strip.

Labor commencing, the cervix was found to be fully dilated, bag of waters presenting, retraction of the anterior lip going on, and the cicatricial band was felt to be severely stretched during uterine pains. An enormous cicatricial ring an inch and a half thick embraced the entire ostium vaginæ, absolutely inelastic, limiting the diameter of the os to two inches, with no possible increase save by cutting or tearing. The entire pelvic floor was cicatricial, hard, inelastic, resisting, unpliant. This ring extended up around and behind the symphysis; it was impossible to introduce the hand beyond the ring, much less to hope to deliver a fœtal head through it.

The urethra was found divided in the middle, so that a sound introduced in the meatus passed into the

vagina. The posterior urethral opening could not be seen, but was felt under and behind the pubis, close to the anterior lip of the cervix; the bladder could be seen distended above the pubis, covering irregularly a space one inch below the umbilicus and two and a half inches to the right and left. A soft catheter was introduced with difficulty and the urine drawn off; the fœtal condition was excellent, the cervix quite fully dilated.

Labor began at 1:30 A.M., February 14th; presentation, L. O. A.; bladder full and high; head engaged; moulding complete; transverse diameter of pelvis much reduced; the vaginal cicatrix prevented direct measurement; subpubic arch was 2 inches wide; distance between the ischia, 4 inches; distance of coccyx from subpubis, 3 inches; conjugata vera 3½ inches.

The vagina was irrigated with bichloride solution at 11 A.M.; bowels moved freely during the morning.

The longitudinal cicatricial band running down from the posterior cervix was cut; numerous incisions were made in the vagina to right and left of the rectum. This enlarged the vaginal opening one inch, although leaving everything very rigid. The amnion was ruptured and forceps applied. The justifiable limit in traction with safety to the child was employed, the head being in proper position, but no advance was secured. The fœtus was still in excellent condition; version being impossible on account of the rigidity of the vagina, which rendered introduction of the hand or arm out of the question, symphyseotomy was accomplished in a few moments. The head descended one-half inch following section and separation of one and one-half inches ensued. After considerable difficulty and severe forceps traction, the head was delivered, the child being in a most vigorous condition. Not more than three or four ounces of blood were lost in the entire delivery. My subcutaneous method, as employed in four previous cases, was used in this case with entirely satisfactory results.

The wound and vagina were packed with iodoform gauze, and then patient placed in a stretcher suspended in bed, the canvas being cut under the buttocks, with adhesive straps bound about the pubes and trochanters. Great difficulty was experienced in bringing the symphysis together, owing, probably, to the rigidity of the soft structures.

This woman must have been frightfully handled in her first labor, with granulation healing of the vagina.

The child, a male, weighed eight pounds and six ounces; its pulse was 120 after birth.

The measurements of the fœtal head were as follows:

Biparietal, with head fully moulded	3¾ inches.
Bitemporal	3½ "
Fronto-mental	4 "
Occipito-frontal	5 "
Cervico-bregmatic	3¾ "
Suboccipito-bregmatic	4 "
Occipito-mental	5½ "

Thirty-six hours after delivery the gauze was removed from the pubic wound, and the parts were gently washed with bichloride solution.

The catheter was not needed, the urine not being retained by the bladder. Temperature elevation of from one to three degrees kept up, the cause being a double slough of the vaginal cicatricial tissue. A fistula formed just within the internal anal sphincter, and a slough from the base of the bladder was thrown off.

The pubic wound was in no way infected, but healed up promptly, being entirely closed in eight days from delivery. The patient was slowly improving four weeks from delivery, when pneumonia supervened and she died March 18th, thirty-three days after

delivery. The child is living and well, now two months old. Without desiring to strain conclusions in the slightest degree, I can fairly say that the one error in the case was in not doing a Cæsarean section instead of a symphyseotomy. I can fairly say that death in no way can be charged to the pubic section, but to the tremendous cicatrix in the vagina. I did not realize when I made pubic section how great the resistance of the soft parts would be.

The behavior of this case is the strongest argument yet shown in favor of my method of operating. Here was a vaginal condition that in either Morisani's or Pinard's method would almost certainly have infected the pubic joint. My method has now been witnessed by four or five of our most prominent obstetricians, and has been highly approved without exception. It has greatly reduced the chances of hemorrhage, not more than from three to four ounces of blood being lost in any case of the six now on record; it has very much lessened the liability of infection of the joint and renders section of the joint much simpler than before. The real dangers in symphyseotomy are not in the pubic section, but in the delivery of the child after separation of the joint. Laceration of the vagina appears from a study of the records to be the most prominent danger. I must emphasize the importance of securing the fullest dilatation of the cervix before making pubic section; otherwise, in pulling with the forceps the undilated uterus is dragged down into the pelvis, filling its space and pressing the depressed bladder into the diastasis, also causing the tissues in the region of the bulbi vestibuli to swell with blood and preventing their stretching, thus causing them to burst and give a starting tear to the anterior wall of the vagina. The operator must also be on his guard to secure by the forceps, if necessary, anterior rotation of the occiput, the alteration in the form of the pelvic cavity resulting from pubic separation preventing the customary act of the sacro-sciatic ligaments in throwing the parietal eminence forward. There is a distinct tendency at times for the head to remain in the transverse occipital position. I must speak emphatically in favor of forceps delivery as against version following symphyseotomy, if the head is presenting normally. In the table previously referred to there were 112 cases, of which 82 were delivered by forceps, and 14 by version; 4 being by both and 12 not reported. Fætal deaths when forceps were used were 7 out of 82 and by version 5 out of 14 cases.

My paper upon the after-effects of successful symphyseotomies in America, in the *Polyclinic Journal*, gives a remarkably favorable report. Not a single patient has been permanently disabled, and but one has a persisting fistula, which is rapidly closing. No disablement of permanent character has resulted. Further comment seems useless. Symphyseotomy has established itself on the unshakable rock of demonstrated fact, and comes to us a welcome choice in preference to craniotomy or Cæsarean section, and in most cases of induced labor also.

The Poison of Tetanin.—A writer in the *Journal of the American Medical Association* writes that Brieger has found and isolated a ptomain from the tissues in a fatal case of tetanus which he named tetanin. This was obtained also from cultures of the bacillus by Kitasato and Weyl. This substance kills animals with the characteristic symptoms of tetanus, but is not the substance to which is due the intense intoxication of tetanus, and Brieger himself obtained a toxalbumin of much greater toxicity. This toxalbumin, the chemic relations of which we do not know, is probably only an impure form of the specific toxin—a mixture of the precipitated albumins and the toxin.

THE VALUE OF CARBOLIC ACID IN SOME CATARRHAL DISEASES OF CHILDREN.*

BY S. HENRY DESSAU, M.D.,

PROFESSOR OF PEDIATRICS, NEW YORK SCHOOL OF CLINICAL MEDICINE.

DURING the past autumn and winter I have treated with carbolic acid nearly three hundred infants and children complaining of a group of catarrhal symptoms, which I have classed as being of infectious origin—in other words, a mild, irregular type of influenza. Altogether the results in these cases have been so nearly uniform and satisfactory that I regard them as well worth reporting.

In the beginning of the past season many children affected similarly to these now reported were treated with a mild sudorific and expectorant mixture, a combination of liquor ammonii acetatis, ipecac, ether, and syrup of senega, but it was soon observed that the prompt success which had always been previously experienced in like cases did not follow. This led me to become suspicious of the nature of the complaint until later on its infectious character was fully recognized. About that time my attention was directed to the adoption of carbolic acid as a remedy, largely through a most instructive article on its use published in the *Medical Times* for November, 1895, by my friend, Dr. James Robie Wood.

Perhaps it is familiar to all physicians who have been many years in practice that after using a certain remedy for a period of time we discard it for some new remedy grown more popular, until after a lapse of time we return to the use of our old friend with renewed confidence. I, like many other older members of the profession, had years before used carbolic acid largely in the treatment of various infantile complaints depending upon a low order of germ infection, such as summer diarrhœas, erysipelas, pertussis, and slight congestions of mucous membranes. When influenza made its appearance in this country eight years ago, however, the newer coal-tar derivatives were then in vogue, and, as the type of the disease was much severer than now, we easily found ourselves using an apparently well-indicated remedy, like antipyrin, phenacetin, or salicylate of sodium, as they were analgesic as well as antipyretic. A wide experience with these coal-tar products in the presence of fever soon taught us to be careful of their depressing effects upon the heart, which is brought about through their influence upon the hæmoglobin of the blood, converting it into a methæmoglobin, as well as by interference with complete conversion of increased waste products incidental to the fever process, the latter being now regarded as a conservative manifestation to get rid of the disease poison. A reaction in our therapeutics of influenza had thus begun to occur, and I was one of those who preferred to adopt an eliminative method of treatment, as outlined in my remarks on the discussion of this disease before the New York County Medical Society in November, 1891.

At the present time, however, the mild type of the affection, as manifested in children by a dry cough, worse at night, with very few coarse ronchi heard on auscultation, either alone or together with few dry subcrepitant râles in localized areas, scattered over one or both lungs, alternating on slight exposure to changes of atmospheric temperature, with a coryza or possibly a diarrhœa, did not seem to call for so active a line of treatment as severe cases, or those attended with prostration and pneumonia.

The good results obtained with carbolic acid in the cases of dry bronchitis led me later on to extend its use with like good results to other cases, those in which, for instance, a post-nasal catarrh with rise of rectal

* Read before the Society for Medical Progress of the West Side German Dispensary, May 9, 1896.

temperature two or three degrees, or an cedematous condition of the mucous membrane of the soft palate and post-pharyngeal space was present, the latter extending in some instances to the larynx, and producing aphonia and even stenotic respiration.

It is, however, for the dry irritant cough or bronchitis of influenza that I especially wish to recommend carbolic acid as an almost specific remedy. Thompson describes the cough of a bronchitis as either irritant or expectorant. Clinically the irritant cough is not a succession of sounds linked together as in the expectorant cough, but is dry and barking, or like the cough of a sheep, "schafhusten" of the Germans. This feature of the cough alone would tend to indicate the germ origin of the bronchitis. Moreover, this condition with scant secretion of mucus lasts longer than in the first stage of an ordinary bronchitis, in which the normal secretion is first diminished in quantity and afterward increased with alteration in quality. In fact it may continue until the cough entirely disappears, without any subsequent increase of secretion. In the mean while the physical signs are out of all proportion to the amount and effort of the cough.

The elevation of rectal temperature before mentioned was observed in these cases to continue for four or five days. Another characteristic feature in these cases under consideration is the appearance of the tongue. It is slightly covered with a white, moist or glazed-like fur, less at the tip and sides than at the base and centre. Through this gum-like coating, as if delicately laid on with a brush, the fungiform papillæ project, reddened and often enlarged, giving the tongue the appearance, as some English writers have described it, of a white strawberry. This condition of the tongue I regard as entirely characteristic of this form of germ infection of mucous epithelium, and a diagnosis of influenza is possible from its presence alone, by any one thoroughly familiar with its appearance.

It will be recognized at once that this description is not that of an ordinary subacute bronchitis, in which the lungs on auscultation may show different varieties of râles, either dry or moist, but without any rise of temperature after the second day, unless complicated with a pneumonic process, or an exacerbation of the disease depending upon further extension into other bronchi.

Granting, however, that my cases were only those of an ordinary subacute bronchitis, and that the condition of the tongue, loss of appetite, and general malaise went for naught, the fact remains that the cough persisted in spite of the usual expectorant treatment that was previously entirely successful in ordinary bronchitis. Hence I was forced to seek some other mode of treatment, and, as I said before, my thoughts most naturally turned to carbolic acid. And why not? Have not the tar preparations been used in pulmonary catarrhs from traditional times? And was it not known in the early days of the use of carbolic acid that it was partly eliminated from the lungs in the same manner as tar and the terebinthines? Was not carbolic acid used by many of us in the treatment of pulmonary tuberculosis with fairly good results, long before the introduction of creosote for this disease, upon the assumption of its antiseptic action on the pulmonary mucous membrane? Finally, is it not the basis of all the other coal-tar derivatives and the simplest form for medicinal use?

"The end crowns the work." My choice, so far in my experience, has happily proved most satisfactory and my theory apparently correct. Many of these cases of annoying cough in infants and children have been relieved in two or three days, all of them certainly within a week, whereas in the beginning of the

season cases of this class were not relieved sometimes in three weeks or even longer.

The preparation I have used is a one-per-cent. solution of the chemically pure acid, to which is added a small quantity of glycerin or simple syrup. The dose for children under five years of age is a teaspoonful, equal to between one-half and two-thirds of a drop of carbolic acid. This is given every two hours until improvement is decided, when the intervals may be increased until the cessation of all symptoms is complete. The taste is not unpleasant, though now and then some objection may be made to its administration at first, but with a little firmness this soon gives way. Perhaps it may be well to throw out the hint that a word of assurance on the part of the physician to the parent as to the nature of the remedy will serve to secure their confidence, as in the commencement of my present experience several parents, detecting the drug from the odor of the solution and knowing that carbolic acid was a powerful poison, hastened back to the druggist to learn if some mistake had not been made in dispensing the prescription. One woman even accused me of wishing to kill her child. A friend has suggested to use the word "phenic acid," as being not so familiar. I can certainly recommend this simple treatment for influenza bronchitis, or even influenza of a mild type, with perfect confidence. So far I have observed no bad effects from the remedy when used in the dose and manner I have stated. I am well aware that Jacobi and other writers on pædiatrics, while recommending carbolic acid as an internal antiseptic remedy, urge so much caution as to its irritant effect upon the kidneys as to debar the cautious physician from employing it.¹ All of us who have seen cases of poisoning from carbolic acid are familiar with the smoky color of the urine, which is said to be due to the presence of hydroquinone, a product of oxidation of the acid from its combustion in the body. This in itself, to my mind, is no proof of any lesion of the kidney, for there is every reason to believe that it occurs in the blood circulation. As to any other evidence of renal lesion, such as albumin and casts, I know of none. Thus far, out of nearly three hundred cases treated with carbolic acid in the manner I have mentioned, I have seen only one case of nephritis occurring during its use, and that one I do not attribute to the acid, but to a complication of influenza, which we now know may cause nephritis, the same as scarlatina, diphtheria, or measles. Medical friends have informed me of cases of influenza nephritis occurring in their practice this season in which no carbolic acid had been given.

In regard to the *rationale* of its therapeutical action, I can only say that I believe carbolic acid to be a typical antiseptic. By this I do not mean that it destroys any germ or antidotes any toxin as a germicide is supposed to do, but that it renders the blood and tissues of the body, the soil upon which the germ thrives, sterile, thus checking any further production of the toxin. That carbolic acid can and does permeate the blood and tissues of the body can be convincingly demonstrated to any one who has ever been present at an autopsy where death was caused by a toxic dose of the same. The blood is dark and uncoagulated, and gives a decided odor of the acid. As to the daily amount of carbolic acid employed being sufficient to affect the blood and tissues so as to prevent the further growth of the influenza germ, I cannot furnish any positive proof or demonstration to corroborate my explanation of its antiseptic action. But, besides the happy therapeutical results that follow its use, it may be stated that there is more than a mere possibility that this assumption is true, for M. Raulin,

¹ Chemically carbolic acid is regarded as a phenyl alcohol, and, like the other alcohols, is largely excreted by the kidneys.

a French scientist, quoted by Bacigalupi, has very prettily shown that some of the lower order of germs are most sensitive to the action of certain elements that are either necessary or prejudicial to their growth. Thus, for example, the *aspergillus niger*, order of *mucoedinae*, is increased in growth by the presence of zinc in a culture medium seven hundred times its weight of the metal contained therein, while one-sixteen-hundred-thousandth of a grain of nitrate of silver arrests its growth abruptly, and it will not even begin to grow in a silver vessel, so sensitive is its prejudice toward this metal. Who shall say after learning such facts that analogous conditions may not exist in weak pathogenic germs, such as those causing influenza, erysipelas, summer diarrhoea, etc., toward carbolic acid, even in the small quantity I have recommended, since the blood becomes impregnated to that extent?

I have observed that after a few days' use of carbolic acid the transpiratory function of the skin becomes most active. In addition to the slight physiological action of carbolic acid upon the sweat glands, I think this can be explained by regarding the normal restoration of eliminative function to have occurred as soon as the further generation of the *materies morbi* has been checked. This is nature's own method of re-establishing the healthy state.

Since the foregoing was written, I find that Brunton, in his work on "Pharmacology and Therapeutics," 1885 edition, p. 690, recommends carbolic acid as a most serviceable remedy in precisely the class of cases that I have here reported. Consequently I cannot lay any claim to originality in the treatment of influenza catarrhs with carbolic acid other than in the manner of administration of the remedy. Brunton recommends the use of a weak solution of carbolic acid to be inhaled in the form of a vapor or spray, while I give it internally, a decided advantage in my estimation, especially in the treatment of children in a dispensary practice.

In conclusion it may be truthfully said that in carbolic acid we have a most valuable remedy when properly used. This statement does not apply merely to children nor to influenza affecting them, but to adults and diseases affecting them as well. History in medicine, as in politics, repeats itself, and I believe the day is not far distant when we will be found using carbolic acid as frequently as in years past, but with a better knowledge of its true value than we formerly possessed.

144 WEST EIGHTY-FIFTH STREET.

Colles' Fracture.—Dr. Morgan, before the Medical Association of Georgia, April 15, 1896, says that every case of Colles' fracture can be readily reduced by strong, forced dorsal flexion, effected during anæsthesia. He considers Wyeth's modification of Pilcher's dressing the best. The plaster-of-paris dressing is preferable in old people in whom there is a firm impaction which the surgeon does not care to break up, or in cases in which the fragments are more or less comminuted. It should be applied from the lower border of the metacarpus to the middle third of the forearm, with the patient's hand in the straight position. A straight dorsal splint may be employed but is not very desirable, while in no case should the angular or pistol-shaped splint be used; no splint should be allowed to extend beyond the metacarpus. The fingers should remain freely movable, and limited motion should be encouraged at first, followed later by more active motion. In aged patients in whom there is more or less impaction of the broken ends reduction should not be attempted, as impaction favors the consolidation of fractured bones, and a crooked wrist is better than a failure at bony union.

ETHER AND OXYGEN AS ANÆSTHETICS.

By JOHN L. CORISH, M.D.,

BROOKLYN.

My attention was called to the use of oxygen in connection with ether as an anæsthetic by an article which appeared in a Brooklyn daily paper in December last, describing the results of experiments made in a Brooklyn hospital.

On January 5, 1896, I was called upon to attend a child three days old, who was suffering from a severe capillary bronchitis with marked cyanosis, dyspnœa, and atelectasis of the lungs. A further description of this remarkable case will be reserved for a separate article, but I wish to embody in the present one the result of the administration of oxygen with nitrogen monoxid as an anæsthetic. This mixture was not given for the purpose of producing anæsthesia, but for an entirely different object, namely, the dilatation of the lungs and removal of obstructions of mucus from the pulmonary lobules. On January 8th, the last day of the administration of the oxygen mixture, I gave forced inhalations at four different times, the last being at 3:15 P. M. The child had recovered from the cyanosis, atelectasis, etc., but I gave one additional application, thinking that I would make the treatment doubly sure. The mixture was administered by passing the gases through a globe wash bottle and then into an ice bag, altered and applied in such a manner as to encircle the chin and vault of the skull. The child took the mixture while crying. The pressure used was half an atmosphere, as shown by the gauge on the bottle. The natural color of the skin changed to a rosy hue, distributed evenly over the whole body. The child cried for perhaps half a minute, and the respirations decreased in frequency and depth (they had been thirty-five previous to the administration). As the administration of the oxygen progressed, their character became similar to those of a person suffering from morphine poisoning, as were the symptoms of decubitus, etc., with the difference of the rosy hue of the skin as previously mentioned. Suddenly the breathing stopped entirely. I examined the heart and found the pulse 140, full and regular. The mother became alarmed; she thought the child was dead. I resorted to Sylvester's method for restoration and kept it up for a period of five minutes with no results. While preparing my hypodermic for an injection of brandy, the child gave a deep gasp, a convulsive one, and then let out a hearty yell. From that point on the child's respiration became normal.

As the child lay there with no respiratory movement, with excessive redness of the skin, and natural heart beat, it recalled to my mind the case of a lineman who was shocked with a 700-volt current, amperage unknown, whom I attended last August. The positions in this state of anæsthesia of both man and child were the same; the character of the heart beat was the same. There were no respiratory movements in the case of the lineman for twenty minutes; he recovered under the D'Arsonval treatment. The question to be answered is: What was the condition of the child during the period when respiration was absent? Had it been deprived of any of its natural resources? No. Then, what rendered it oblivious to the rough usage and treatment which we adopted to restore it to consciousness? I had simply introduced into its system a superabundance of oxygen; in fact, to such an extent that the system was saturated, and the respiratory centre satiated. The system was supplied with an excess of oxygen stored up in the circulating fluid, as is done by the mother for the fœtus in utero. The child did not have to use its respiratory apparatus to sustain life until the superabundance of oxygen had been used up in the bodily requirements; and when it

had been used up what happened? Any medical man, who has watched the newly born infant knows how with a gasp of deepest proportions the new arrival begins the struggle of life—with a yell. That is what occurred in this case. When the child found it could take care of itself, it ceased crying. I am positive from the tests I made that the child was totally unconscious during those seven minutes, and that an amputation could have been performed without the child's returning to consciousness until the extra supply of oxygen stored in the system had been used up. This explains how it is possible for an intra-uterine amputation of the arm or leg to take place with the fetus in utero, without giving rise to reflex symptoms on the part of the mother. It may be claimed that the nitrous oxide used to dilute the oxygen was the cause of the anæsthesia, but Wood in his "Therapeutics" positively states that nitrous oxide does not produce anæsthesia of itself, that the effect is caused by a want of oxygen. As a result of their experiments M. Jolyet and Blanche reached the same conclusion. Paul Bert asserts that nitrous oxide as an anæsthetic is destitute of positive qualities. I think these arguments will be sufficient to exclude nitrous oxide as the cause of the anæsthesia in this case.

I have spoken all along of the physiological result obtained in this case as an anæsthesia. Was it anæsthesia which was produced? What is anæsthesia? Dunglison says: "Anæsthesia is the deprivation of sensation and especially that of touch; according to some, paralysis of sensibility; it may be general or partial." All the characteristics of anæsthesia were present in this case without the toxicological symptoms accompanying etherization, which are similar to those present in apoplexy, viz., stertor, dilatation of the pupils, etc. The pupils in this case were normal; there was no sensibility in the eye. Slapping and pinching did not excite reflex movements. From the above I conclude that oxygen is an anæsthetic, and an anæsthetic *par excellence*, if given in sufficient quantities. This brings me to the administration of ether and oxygen in combination for anæsthetic purposes. The following case will bear out my conclusions:

Edward H—, seventeen years old, weight 135 pounds, residing at Fort Hamilton, was severely injured on February 9, 1896, by a falling chimney. Chloroform was used in the preliminary examination. The patient was suffering from severe shock at the time; still he had vitality sufficient to make a determined resistance to the administration of the chloroform, which was given by Dr. —, ambulance surgeon of Sency Hospital. The excitement was very marked; the anæsthetic was administered for forty minutes, and recovery did not take place for three hours. On February 17, 1896, in company with Dr. Blackmar, of Bay Ridge, I put the right lower extremity in a Buck's extension (for fracture of the femur) and attended to other injuries at the same time. I used a compound of oxygen and nitrous oxide, the gas being passed directly through the ether in the wash bottle without the intervention of a water wash bottle.

The apparatus used was the identical one employed in the case of the child above noted. The patient was told to elevate the hand; he did so, and kept it up for eight minutes, when it dropped. Anæsthesia was incomplete until three minutes after the dropping of the hand, the mixture still being applied. The anæsthesia was sustained for one hour and twenty minutes under the following conditions: Inhaler applied at 11:30 A.M.; complete anæsthesia at 11:41, inhaler removed; reapplied at 12:15 P.M. for three minutes; interval of twelve minutes; reapplied for four minutes and then discontinued altogether. Patient opened his eyes at 12:48 P.M. and fully recovered at 1 P.M. At this point I would like to call attention to the relatively small

amount of ether employed, namely, two ounces and six drachms, the patient being in a condition of etherization for one hour and twenty minutes. This amount includes loss from handling, and necessary waste by volatilization, etc. All articles published previously on this subject have shown a far greater proportion of ether used for the length of time the patient was in a condition of etherization. This may be accounted for in several ways: 1st, owing to the imperfect construction of the apparatus; 2d, the continued application of the mixture when unnecessary; 3d, the oxygen, having first passed through water, is not capable of absorbing as much ether as it would if passed directly through ether without the intervention of an intermediate wash bottle; 4th, instead of the ether vapor and oxygen being thoroughly mixed before reaching the cone, the ether had been placed in the cone itself and the oxygen passed through it, *i.e.*, an attempt had been made to unite the oxygen and ether in the cone itself, a quantity of the ether thereby not being uniformly mixed with the oxygen and rendering a certain amount of the ether unnecessary.

I would call special attention to this important point: that there was an entire absence of excess of mucous secretions in the nares and pharynx. At no time was there any cyanosis, neither were the extremities cold. There was an entire absence of vomiting and nausea. Patient had partaken of two eggs, two slices of toast, and a cup of coffee at 8:30 A.M., three hours previous to etherization. Fifteen minutes after recovery from the effects of the ether he was given a cup of coffee, which did not in the slightest degree disturb his stomach; half an hour after the recovery he fell into a doze and slept for four hours. Dr. Blackmar tells me that he gave the patient morphine, one-eighth grain, and atropine sulphate, one-two-hundredth grain. I do not think that this alone would have caused such refreshing sleep. When the patient awoke he immediately sat up in bed. There were no symptoms of exhaustion following the operation.

Care should be taken to use an oxygen prepared otherwise than the ordinary commercial oxygen which is largely advertised and sold as pure oxygen, as much of this gas is unfit for human consumption, being saturated with chlorine and other deleterious gases. Pure oxygen itself is unsuited for the purpose of anæsthesia because of its dense specific gravity, it not passing through the capillary blood-vessels when undiluted. It has been repeatedly demonstrated that animals cannot live in an atmosphere of pure oxygen. Nature kindly points the way by directing us to the use of nitrogen, which forms such a large percentage of the air we breathe; it therefore follows that we should imitate nature by using nitrogen monoxid as a vehicle for carrying the oxygen, it being lighter in its specific gravity and being exquisitely applicable for this purpose. The mixture that has given me the most satisfactory results is one composed of two parts oxygen and one part nitrogen monoxid. A point I wish to make here is that if one is sure of the quality of the oxygen, it is advisable to pass it directly through the ether, instead of first passing it through water, and do away with the pouring of the ether into the inhaler, generally constructed of paper and towels. The advantages are that the mixture is more thorough, the gas is not loaded with watery vapor in addition to the ether, the lungs can more readily absorb the mixture, and there is very little loss, especially when given through a suitable inhaler. At the time that these experiments were conducted I sought in vain for an inhaler with which to carry out the administration of the oxygen. Within a short time an inhaler has been brought to my attention, which is infinitely better than the one I im-

provided. I believe this inhaler is on the market and can be obtained from any drug store where oxygen is for sale.

Oxygen as an Anæsthetic.—An extended series of experiments in the employment of ether, chloroform, nitrous oxide, and oxygen leads me to the following conclusions:

(a) The excitement stage due to the cutting off of the oxygen from the circulation, thereby causing nervous reflex muscular movements and irritation of the air passages, is abolished when the oxygen is added, on account of the blood receiving sufficient oxygen.

(b) The cyanosis which is caused by the reflex paralysis of the vasomotors, thereby allowing dilatation of the venous and contraction of the arterial blood vessels, due to a lack of oxygen at the nerve centres, is little marked or entirely absent.

(c) That there is no increase of the mucous secretion is due to the removal of the cause of irritation and congestion of the mucous membranes. This nuisance, which in many instances is intolerable, particularly in the surgery of the nose and mouth, has in some cases in which the secretion entered the larynx caused dangerous symptoms of asphyxiation or subsequent pneumonia.

(d) The vomiting and nausea, owing to the congestion of the stomach and irritation of the palate, are alleviated and this of necessity does away with the danger of food becoming lodged in the air passages.

(e) The anæsthesia may be continued without stertor. This symptom, due to muscular paralysis of the palate, is not a necessary accompaniment of anæsthesia. It shows that excess of the anæsthetic is being used. The palate is controlled by both voluntary and involuntary "forces." This symptom is a very good guide for the operator to go by.

(f) The recovery from anæsthesia is quicker and more complete, owing to a minimum of ether being used. The recovery cannot be hastened by the employment of oxygen separately after the operation.

(g) The amount of ether used is just sufficient to keep the patient under its effects, and when thoroughly mixed with the oxygen (compound) no serious symptoms can result. The patient will not breathe at all if oxygen be given to the point of saturation, and therefore no more ether will be taken in than is required until the respiratory centre calls for more oxygen.

(h) Owing to the amount of oxygen stored up in the system by this method, the etherization may be discontinued at times for from fifteen to thirty minutes and complete anæsthesia may be readily and quickly reinduced in thirty seconds, if occasion requires, by application of the previous method. This advantage to the specialist in pharyngeal operations must be apparent.

(i) Owing to the character of the heart beat not being much altered, the combined anæsthetic can be given with comparatively less danger in cases of stenosis and insufficiency of the cardiac valves.

Finally, I wish to state that I believe and think it will be borne out by subsequent experiments that when the oxygen is given in superabundance in connection with ether, a double effect will be produced, *i.e.*, an anæsthesia from ether primarily and from oxygen secondarily. Ether is eliminated from the system by means of the lungs through respiratory efforts. If we can supply sufficient oxygen to the system, so that the respiratory centre is not irritated or rendered dormant, we prolong our anæsthesia until such time as the ether is split up chemically and passed off through the skin. Another point to be observed in the use of oxygen with ether is this: in extensive operations in which great loss of blood is to be expected and it is usual to constrict the limbs, it would be advisable to ad-

minister oxygen before the tourniquet is applied, so that when the blood is allowed to reenter the circulation it will be in a condition more in conformity with that of the rest of the body.

With regard to the anæsthetic power of oxygen when properly induced, in its application to surgery, I am positive that it will be of very great value in operations on young children who may require surgical interference of short duration. Operations about the mouth and nose could be performed to the entire satisfaction of the operator, as the apparatus could be dispensed with immediately on the cessation of respiration. Under the condition of oxygen anæsthesia, so to speak, the system is saturated with oxygen, the blood in the veins assumes an arterial hue, and the surgeon would have difficulty in recognizing venous from arterial hemorrhage, but this would be insignificant in comparison to the benefits obtained.

It is to be hoped that further research into this very important subject will prove that as we perfect our apparatus we will approach the point where we will use the minimum amount of ether and the maximum amount of oxygen.

I have no doubt that this article will be severely criticised, and in fact would be surprised if it were not. I would ask my critics, however, before subjecting the article to adverse criticism, to make their experiments in accordance with the plan I have adopted.

NINETY-SECOND STREET, NEAR THIRD AVENUE.

Progress of Medical Science.

Fistulæ in Ano.—Dr. Metcalf (*Physicians and Surgeons*) says: "Fistulæ in ano may be caused by penetrating wounds, by suppuration arising from injury to the mucous membrane from foreign bodies in the fæces, or from catarrhal dysenteric or gonorrhœal inflammation extending into the submucous tissue. The suppuration may start in hemorrhoids, occasionally caused by improper methods of treatment."

Sciatica.—Dr. C. Negro (*Semaine Médicale*) treats sciatic neuralgia by digital compression of the painful points along the course of the nerve, and has almost unvarying success. Out of one hundred and thirteen cases he had good results with one hundred. The patient reclines in bed with the lower limbs in a state of complete muscular relaxation. Compression is first made at the point of exit of the nerve, which is usually the most sensitive point. The right thumb is placed in contact with the painful point, and over the right thumb the left is placed; the pressure must be energetic and last about twenty seconds. Lateral pressure is made at the same time, the thumbs remaining in a fixed position. Other painful points are successively treated. The *séances* of compression are repeated every other day. Ordinarily six *séances* suffice for a cure.

Pental and its Administration.—At a recent meeting of the Society of Anæsthetists Dr. Prince Stallard read a paper on this subject (*New York Medical Journal*). Pental, he said, was a clear, mobile, colorless liquid, having no marked taste, but producing a slight burning sensation when it was placed on the tongue, and a slight irritation at the back of the throat, which, however, soon disappeared. It was exceedingly volatile and highly inflammable; it had no escharotic action when dropped on the skin, and its smell was somewhat pungent, but not disagreeable, as patients never complained of its odor. At the ordinary temperature of the room it was so volatile that it was nec-

essary to administer it by the closed method, with the admission of as little air as possible. If exhibited on a piece of lint, as was usual with chloroform, a large quantity of the drug was required. In one hundred and forty-eight cases Clover's portable ether inhaler had been used. Two drachms of pental were poured into the reservoir, the indicator placed at 0, and the patient encouraged to fill the small bag with his expirations; the indicator was then turned rapidly but evenly to 3; rarely was it necessary to turn to F. Pental was thus given more rapidly than was advisable with ether, and attention had been directed to the absence of coughing, struggling, and fighting for breath, so characteristic when the latter drug is given alone without the previous exhibition of nitrous oxide gas. No restriction had been placed on the patients with regard to diet, and in only one case had there been after-vomiting. The clothing should be quite loose around the throat and abdomen so that the thoracic and abdominal movements could be quite free. All the administrations had taken place at about 10 A.M. In all the cases the patients had been seated in a dental chair, the head having been placed in an easy position midway between flexion and hyperextension. The horizontal position, said Dr. Stallard, would be much safer, as signs of cardiac failure had not infrequently occurred in the cases quoted, pental, in this respect, resembling chloroform. When this drug was inhaled the pulse was at first quickened, and likewise the breathing, and then the pulse became fuller and bounding, with dilatation of the capillaries of the face, which was evinced by extreme flushing, similar to that observed when nitrite of amyl was inhaled; swallowing movements were observed, but never any coughing or struggling; screaming might occur, and dreams of a pleasant nature were frequently experienced. Spasms, tonic and clonic, were occasionally present in the arms or in the legs. The lid reflex was usually present unless the anæsthesia was deep; when the patient was deeply under the influence of the drug the pupils were dilated and the eyeballs turned upward under the upper lids, and, in some cases, the conjunctival vessels were prominent and congested; the arm when raised dropped helplessly to the side. At the height of anæsthesia the pulse became small, and might be running. There was no cyanosis or diskiness of the features, and stertor was very rare. Micturition and defecation had never been observed. Opisthotonos and twitchings of muscles had been noted in a few cases, the patients having generally been tranquil. The breathing could hardly be heard, and this, said the author, constituted one of the dangers, and, in this respect, pental again resembled chloroform. Recovery was extremely rapid, and was not followed by any stupor or drowsiness. As a rule, there were no after-effects, and the patients felt quite well three minutes after the removal of the face piece, and were able to walk out of the house. One case only of vomiting had occurred and three or four of nausea; slight headache had been noted in a few cases, but this had rapidly passed off. The average time required to produce anæsthesia had been fifty-six seconds, and the average anæsthesia obtained had lasted for seventy-six seconds. The pre-anæsthetic stage had varied from thirty to one hundred and twenty seconds and the anæsthetic period from twenty-five to two hundred and ten seconds. The advantages maintained for pental, said Dr. Stallard, were: 1. Longer anæsthesia than nitrous oxide gas yielded. 2. Simple apparatus. 3. No struggling, coughing, or dislike to the drug. 4. The small amount required, which averaged two drachms. 5. Rapid recovery. 6. The absence of after-effects. The disadvantages were: 1. The insidiousness of its action—an overdose could easily be administered. 2. Noiseless and

shallow breathing. 3. Screaming. 4. The sudden cessation of respiration. 5. Sudden cardiac failure.

Dr. Dudley Buxton, speaking of the mortality following the administration of pental, said that Dr. Stallard had given one case out of one hundred and forty-nine, but he doubted whether it had really been due to pental. Gurlt had given three deaths in six hundred administrations, and Snow had given two in two hundred and thirty-eight cases. One of the difficulties in working with amylene and pental, he said, was the presence of impurities. Before we could accuse pental of causing deaths we must be sure it was pure pental and not some mixture of drugs simulating it. In all probability much of the pental at present supplied was impure. One German observer had found albuminuria and hæmoglobinuria occurring in many cases within three or four days after the administration. Pental, so far as we knew at present, was a most useful drug, but it possibly and probably possessed grave disadvantages from its tendency to affect respiration, perhaps through spasm of the glottis and of the diaphragm. In the cases of death it was to be noted that these had arisen from failure of respiration, while the heart had continued to beat for some minutes afterward. A marked injustice might easily be done to any new anæsthetic if, because cases of death had occurred in the early days of its administration, its use was therefore discarded.

Mr. Joseph White said that forty years ago he had used amylene extensively, principally for the extraction of teeth, and had found it a charming anæsthetic, quick in its action, with no after-effects, and liked by the patients. When it had been used for longer operations he soon found that alarming symptoms had been very apt to arise, and feeble respiration and circulation had occurred very suddenly, so that he had discarded the drug, as he did not consider it as safe as chloroform.

Dr. Silk was struck with the similarity of the remarks of Dr. Stallard's cases with those he had himself published as occurring when bromide of ethyl was administered, and, given the change of name in the two records of cases observed, it would be difficult to distinguish the one from the other. He had noticed that with bromide of ethyl decomposition always occurred sooner or later when the bottle had once been opened, and as the clinical symptoms appear so similar he would ask Dr. Stallard whether he had found any evidence of decomposition occurring with pental. He was of opinion that patients should not be in the dental chair, but recumbent during the inhalation of pental, as vascular depression so frequently occurred.

Dr. Augustus Cook said he had been administering pental during the last four or five years; all his cases had been fairly long ones, some of half an hour's extent, but his patients were invariably in the recumbent position. The main advantage of pental was the absence of after-effects; it might even be administered on a full stomach without fear of causing vomiting. The open method was employed in all the cases.

Dr. Dudley Buxton asked if Dr. Stallard could explain why in these recorded cases one would give an anæsthesia of ninety seconds, another of twenty-five seconds, and another of as much as two hundred and ten seconds.

Dr. Stallard said that he had frequently noticed decomposition of the drug. With regard to albuminuria, he had examined twenty-five cases after administration and found no albumin, but it must be remembered that all his cases had been short ones and its effect would not be long enough to injure the kidney. The fall of blood-pressure was marked. With regard to the length of anæsthesia obtained, he was of opinion that there was a marked personal factor in many cases.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

RABBITS AND REFORM.

THE course of reform never did run smooth, any more than that of true love. Its troubles with the perversities of human nature have been chronicled and sung in all the ages. Its purest projects have ever been thwarted by the selfishness of designing men; its converts, like Voltaire's woman, never can be trusted till they're dead; its noblest precepts have ever been flatly defied by sinful humanity. We can therefore imagine that it must have been with almost a sigh of relief that the great and good men known as "The Committee of Fifty" upon alcoholism turned from this stiff-necked and ungrateful species to pursue their studies upon and among the docile and amiable rabbit and the timid hare. But fate still pursues them. The question sought to be decided was the apparently simple one, whether the daily ingestion of alcohol sufficient to produce acute intoxication in hitherto respectable and well-behaved bunnies affected in any way their resistance to inoculation with various pathogenic germs. The investigation was accordingly inaugurated in that native haunt of purity and propriety, the University of Pennsylvania, in its Institute of Hygiene, and under a competent bacteriologist. But no sooner had it begun than difficulties began to spring up on every side. Rabbit nature suddenly developed striking similarities to the human ditto, in point of perverseness. In the first place, under no circumstances and in no combination, neither with the fragrant mint, the cooling lemon, nor the ardent but too constant onion, could bunny be induced to absorb the beverage of his own free will. This, of course, simply confirms our previous impressions as to the very low grade of intelligence possessed by these animals, but it was a very real and serious obstacle to the experiments, for all the alcohol given had to be injected through a stomach tube, which, owing to the resistance offered by the animal, was very apt sooner or later to produce lesions of the gullet or stomach which gave rise to serious and often fatal secondary septic infections.

Secondly, it was found extremely difficult to determine a "standard" dose which could be relied upon to produce acute intoxication in any case, partly from the wide range of individual susceptibility to the drug, but mainly on account of the difficulty of deciding when the animal was actually drunk. The "truly rural" articulation test was, of course, out of the ques-

tion in a species of such reticent habit; their expression is mild but singularly fixed, and couldn't be sillier, and the only sign which the experimenters could find to be depended upon was a staggering gait. Even this, of course, was naturally hard to elicit in a creature of such conservative and earth-loving tendencies, and which keeps nearly as much of its surface constantly applied to the ground as a penny bun does. Thirdly, in order to overcome his positively adhesive equilibrium, it was found necessary to give enormous doses of alcohol, such as would be the equivalent of nearly a quart of whiskey *per diem* for a human being, and these caused such a rapid loss of weight that the experimenter himself declared that the lowering of the resisting power produced was probably analogous to that effected by simple starvation.

The result of the experiments showed that under this vigorous treatment the resisting power of the animals was distinctly lowered for the various strepto- and staphylo-groups (pyogenic), but scarcely affected at all for the typhoid, diphtheria, and other bacilli.

As a contribution to the study of the effects of alcohol upon the human subject these experiments are, of course, to the physician's eye little less than a farce, but we fear that such little discrepancies as those most frankly and fully pointed out by the bacteriologist in charge, in his recent report, will in no way discourage our temperance friends from using the results in their next onslaught upon the drink demon.

A similar investigation is just being carried out upon monkeys, which present the advantages of having no conscientious or other scruples against taking the liquor in almost any form and of being gifted with both a loquacity and an activity of movement which enable them to exhibit the characteristic symptoms of the drug with an almost Hibernian promptness and unmistakableness. However, we fear that long ere the research is concluded the thumbs of the experimenter will look back with keen regret to the days of the blameless and non-belligerent bunny, and that the ideal subject for these experiments has not yet been found.

THE LAW AND ACCIDENT INSURANCE POLICIES.

THE liability of companies insuring against accidents is so often tested in courts of law that it becomes of the utmost importance that the relative positions of plaintiff and defendant should be accurately defined. In the practice of this new branch of jurisprudence numerous decisions have been rendered which aid very materially in the formulation of leading principles of action in given cases, and in the main they may be considered just and reasonable to all parties concerned. That more, however, is to be learned is shown by a case recently before the appellate division of the Supreme Court in the third department of this State. A physician in Essex County sued the Interstate Casualty Company for \$487.50, in consequence of cellulitis resulting from a self-administration of a hypodermatic injection of morphine. In order to base the action upon an accident and bring the occur-

rence under the intent and meaning of the policy held by the plaintiff, a novel and ingenious claim was made. While the physician was driving on his rounds, away from immediate help, he was seized with exhaustion arising from an injury previously received. He accordingly stopped his horse, and while he was administering a hypodermatic injection to himself the horse started suddenly and the needle was driven to an unnecessary depth into the leg. Cellulitis ensued, which disabled him for a period of many weeks. The company refused to pay the doctor, and the Circuit Court in Essex County, before which the case was tried, dismissed the suit on the grounds that the administration of the morphine was voluntary, that the drug had nothing to do with the cause of the inflammation, and, lastly, that the whole difficulty was caused by an unclean needle. From a scientific point of view, the decision was an eminently just one, and the only surprise is that the judgment of the first court was reversed by the appellate court, mainly on the ground that the mere depth to which the needle penetrated might have been an important and leading causative element. It will be interesting to note what will be the result of the recommendation of a trial by jury on the points involved. It will be extremely difficult, in the light of our present knowledge of wound treatment, to prove any relation of cause and effect with the mere depth of the wound, provided a perfectly aseptic instrument was used. The mere starting of the horse was the only element of accident in the case, and had evidently no more to do directly with the after-results than if the animal had been miles away. The slightest prick of a septic needle would have settled the question of infection, no matter how carefully otherwise the instrument might have been used.

The case in point, although only directly important to the litigating parties, is likely to involve questions which may affect the relations of practitioners to patients in defining what may or may not be preventable disasters. An unclean needle deliberately used in administering a hypodermatic injection is by no means an accident.

THE CASTRATION OF CRIMINALS.

IN a paper entitled "The Crimes of Medical Men," in the *Medical Herald* for June, 1896, Dr. W. O. Henry mentions as one of the crimes of which some, no doubt many, of us are guilty is a failure to urge legislation to prevent the marriage of criminals, or to have them castrated. Whether we are to regard such a failure as wrong or not must depend entirely upon whether or not we think the "proposed remedy is one that will the most surely prevent crime."

As to forbidding marriage, most persons of the class referred to are married before they become confirmed drunkards or are known as habitual criminals; moreover, it is by no means certain that they would procreate less if they were not married and had their liberty.

Castration of the "rapist" might fit in with the sense of justice as well as with that of retaliation of

most people, but if the community should reach the conclusion that drunkards and criminals should not leave descendants, it would seem that an effectual means to that end could be found aside from depriving them of organs which are so important as to be characteristic of sex, and which, it is more than likely, are essential in some respects to normal mind and physical health. And then, who shall say that the drunkard and the criminal have fallen so low that they ought as a result of mutilation to be deprived forever of the possibility of redemption through woman's purifying influence? The reason for making a general law condemning these unfortunates to castration is suggested solely by judgment based presumably upon facts, but the facts are not all in or are too uncertain in their application to assure a whole profession that the judgment is final. But if it were proven that procreation by these persons is so baneful to society as to justify steps effectually to stop it, the end could be reached simply by such restraint as would prevent the sexual relation, while incidentally the criminal would be made to forego his crimes and the drunkard his debaucheries. Then, in the event of a mistake having been made by the community, it would not be impossible to undo the injury.

TAPEWORMS OF POULTRY.

THE bureau of animal industry of the United States department of agriculture has recently published a bulletin in which our present knowledge of tapeworm in poultry is presented in a concentrated form, richly illustrated with two hundred and seventy-six carefully drawn figures, while the ample facts are well arranged for reference, offering an excellent foundation for those who desire to take up such investigations. The medical profession and the public can be assured that there are no attending horrors of infection involved in the investigations of Dr. C. W. Stiles, who has compiled this work, and that chicken roasted, boiled, or fried may be prescribed by physicians or enjoyed by ladies without fear or suspicion of danger lurking in this favorite and appetizing dish, for although we must now admit that the presence of tapeworms is very prevalent in turkeys, geese, ducks, fowls, and other birds eaten as food, both wild and domesticated, we have the comforting assurance that none of the tapeworms of birds is transmissible to man, in any stage of its development, and that the presence of tapeworms in the intestines of fowls does not in itself warrant the condemnation of their bodies as an article of food. The life history of the poultry tapeworm agrees with that of other tapeworms: the eggs are contained in the droppings of the diseased animal—the ova are then swallowed by the necessary intermediate host. Within the ova are the six hooked embryos, known as oncosphere; these bore their way into the body of the intermediate host, and are developed into the larval form, known in this case as cysticercoid. This larva, snugly hid in the body of a tempting-looking worm or snail, is innocently swallowed by a turkey, duck, or chicken, and is then developed into the adult tapeworm. One of the most

common of intermediate hosts is the minute little crustacean abounding in pond and lake waters, popularly known as the water flea.

These water fleas are so commonly bearers of the parasites that geese and ducks are found to be infested with no less than five different kinds of tapeworms which have obtained entrance to their bodies by means of the ingested fleas. It is, therefore, a merciful provision of providence that the human family is proof against contagion of this character, which is fatal to so many birds, but the fact nevertheless offers a strong argument for freeing by perfect filtration all drinking-water from contaminations. The treatment for poultry tapeworm is much the same as for those found in man, the chief drugs employed being extract of male fern, turpentine, powdered kalmala, areca nut, pomegranate-root bark, pumpkin seed, and sulphate of copper. Dr. Salmon offers a word of warning advising that the above drugs should be as fresh as possible, as failure in treatment is often due to the fact that old drugs have been used which had lost their anthelmintic value. The suggestion is a good one, and causes us to wonder how often the good work of the physician is rendered abortive by his prescriptions being prepared with drugs which are the remnants of an old stock and impotent for good.

News of the Week.

Dr. Francis Richard Cruise, of Dublin, has recently had knighthood conferred upon him by the lord lieutenant of Ireland.

Camden County (N. J.) Medical Society.—At the regular monthly meeting of the Camden County Medical Society, at Camden, N. J., Dr. J. Chalmers Da Costa read a paper on "Malignant Tumors."

Reducing the Death Rate.—The death rate in Chicago is going to be materially reduced, not by the introduction of needed sanitary measures but by estimating the population of the city at a much higher figure than hitherto.

Individual Cups for School Children.—Dr. Frank P. Connelly, superintendent of the bureau of contagious diseases of Newark, has recommended to the board of health of that city that no drinking-cups or dippers for general use shall be provided in the public schools, and that each scholar shall be required to provide an individual cup or glass.

An Austrian Code of Ethics is now in process of formation. The compilers have just finished with the knotty problem of consultations, and have decided that, in case of two or more consultants being called in, the last one summoned takes precedence over the others. Each consultant in turn must be told what fee the previous one received, and may then value his own services accordingly.

Medical Women in Scotland.—The Marquis of Bute, who is lord rector of St. Andrew's University, has given notice of his intention to move at the next

meeting of the University Court that a woman shall be appointed to the post of assistant professor of medicine and lecturer in physiology at St. Andrew's. It remains to be seen whether the Scotch students will be as unmannerly as their Irish confrères, who threatened to leave the university rather than come up before a woman examiner.

Generous Gift to the Philadelphia Polyclinic.—The trustees of the Philadelphia Polyclinic Hospital have just received \$5,000 from Mr. Barclay Lippincott, to establish a free bed as a tribute to the memory of his wife, Mary Lippincott.

The New Mexico Medical Society, at its annual meeting at Socorro, N. M., on August 12th and 13th, elected officers as follows: *President*, Dr. C. G. Duncan, of Socorro, N. M.; *Secretary*, Dr. H. J. Abernathy of Socorro, N. M. The next meeting will be held in Albuquerque on the second Wednesday in May, 1897.

Norristown (Pa.) Hospital for the Insane.—Dr. Susan J. Taber, who has been for twelve years first assistant physician, has been selected as the successor of Dr. Alice Bennett, recently resigned, as chief resident physician in the women's department of the Norristown Hospital for the Insane.

Would It Were So!—The editor of the *St. Louis Clinique* has made a discovery that will astonish most of our New York readers. He says that "there is one thing in which our Eastern brethren get ahead of us smartly, and that is in collecting their fees. They certainly get the wealth, whether they earn it or not. If you get a prescription you have got to pay for it. It is easy to keep books in New York. Everything is cash and on the gold standard."

The Ninth Annual Meeting of the American Association of Obstetricians and Gynecologists will be held at the Hotel Jefferson, Richmond, Va., Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1896. Railway rates from all points to and from Richmond for this meeting will be one full fare going and one-third fare returning, on the certificate plan. Members on purchasing their tickets must secure from the agent a certificate that they have paid a full fare to Richmond. On reaching Richmond they can obtain a return ticket for one-third of the usual fare.

An Unusual Suit for Damages.—A suit for \$10,000 has been entered by Dr. D. C. T. Watkins, of Pottsville, Pa., against a female patient, who, after refusing to make payment of a bill for the treatment of a compound fracture of the tibia, claiming imperfect setting and shortening, had a skiagraph made of the fractured bone and sent a communication to a local newspaper, stating that the picture showed shortening and deformity due to overlapping of the fragments.

Foreign Dentists in Hungary.—It has for a long time been a disputed question whether dentists who have obtained dental diplomas abroad should be permitted to practise in Hungary. Considering that only qualified medical men are allowed to practise dentistry

in Hungary, and that there is no special examining board for dentistry in this country, the government has declared that for the future a license granted in another country will be valid only if its possessor is a qualified medical man who acquired his diploma of M.D. in one of those universities which are recognized in Hungary.—*The Lancet*.

"Masked Appendicitis."—In the article with this title in the issue of August 29th, it was stated that the evening temperature of the patient ran from 100° to 110° F.; and in the last line the author stated that the temperature never went above 110° F. In each instance it should have been 101° F., instead of 110° F.

New York State Association of Railway Surgeons.—The annual meeting of this association will be held under the presidency of Dr. C. S. Parkhill, of Hornellsville, on November 17, 1896, at the Academy of Medicine, New York City. The secretary of the association is Dr. C. B. Herrick, of Troy.

The Water Supply of Brooklyn.—Many complaints have been made during the past summer of the foul condition of Brooklyn's water supply. An examination of the ponds whence the water is drawn has shown that they are full of decaying vegetable matter and of insects and their larvæ. The water is discolored and has a bad odor and taste. It has been recommended by the health board that the ponds and reservoirs be cleaned and the pipes flushed, without waiting for the natural purification which will result from the cooler weather and the heavy autumn rains.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the two weeks ending September 5, 1896: August 24th.—Medical Director David Kindleberger placed on the retired list, September 2d; Assistant Surgeon H. La Motte ordered to the naval hospital at Norfolk; Surgeon C. Biddle detached from the *Monongahela* and placed on waiting orders. August 26th.—Medical Inspector J. C. Wise and Surgeons J. C. Byrnes and C. Biddle ordered as a board to convene at Annapolis, September 3d, to examine candidates for admission to the naval academy. August 29th.—Passed Assistant Surgeon E. R. Stitt ordered to duty in the bureau of medicine and surgery. August 31st.—Passed Assistant Surgeon C. H. T. Lowndes detached from the naval hospital, Philadelphia, and ordered to the Washington navy yard; Assistant Surgeon L. Morris ordered to the naval hospital, Philadelphia. September 3d.—Assistant Surgeon G. D. Costigan ordered to the naval laboratory for instruction.

Dr. Thomas Gallagher, the alleged dynamiter who was sentenced to a life imprisonment in England thirteen years ago, on purely circumstantial evidence, has just been released and arrived in this country last week. He has been found to be incurably insane, and was removed to a private asylum a few days after his arrival. He was graduated from Bellevue Medical College in 1880, and had a large practice in Brooklyn before he went to London. He became insane dur-

ing his life in prison, and is said to bear marks on his body of ill-treatment. It does not follow, however, that he was badly treated, for the tissues of the insane are exceedingly vulnerable, and Dr. Gallagher's injuries may have resulted from the use of only such force as was necessary to restrain him.

Typhoid Fever from Ice Cream.—An outbreak of typhoid fever occurred during the latter part of July in the town of East Barrington, N. H. The cases were all traced to a single source. The first case was an unrecognized one, the patient being unwell but helping about the house and doing part of the milking. It is supposed that he must have in some way contaminated the milk, as by going to stool and not washing his hands before returning to his milking. The water supply was carefully examined and found to be all right. On a Friday evening a party was given at the house and the guests ate of ice cream made at home from the milk supply above referred to. Within the next ten or fourteen days fourteen of the guests came down with typhoid fever—eight in the town of Barrington, of whom one died; two in Lee; one each in Dover, Rochester, and Woodbury, N. H., and one in Haverhill, Mass. All of these out-of-town cases were guests at the party. No other cases occurred in the town, and all were partakers of the cream.—*Boston Medical and Surgical Journal*.

Obituary Notes.—DR. ELSWORTH F. SMITH, one of the oldest physicians of St. Louis, died at Fort Missoula in the early part of August. He was born in St. Louis and was graduated from the St. Louis Medical College in 1848. After studying four years in Paris he returned to his native city, where he practised until a few years ago. He was seventy-three years old. His death resulted from injuries received while trying to extinguish some burning curtains.—DR. ALEXANDER BUCHANAN, of this city, died on September 2d, of pulmonary tuberculosis. He was born in Glasgow, but while still young came to this country. He was graduated in medicine in Glasgow in 1860, and also from the New York Medical College in 1862. He had lived and practised in New York since that date. He left a widow and three children.—DR. HULL ALLEN, of Milford, Conn., died a short time ago at his home in that town. Dr. Allen was in his ninety-seventh year, and until recently was in the active enjoyment of good health.—DR. ABRAHAM LIVEZEY, the oldest physician in Bucks County, Pa., died at Yardley on August 31st, at the age of seventy-five years. He was graduated from Princeton College in 1842 and from Jefferson Medical College in 1844. He was at one time professor of obstetrics in the Woman's Medical College of Philadelphia.—DR. SYLVANUS S. MULFORD, of New York, died suddenly of heart disease on September 9th. He was born in 1830, and was graduated in medicine from the College of Physicians and Surgeons in this city in 1856.—DR. WILLIAM M. McLAURY died suddenly at his home in this city on September 8th. He was born in 1830, and received his medical degree from the medical department of the University of the City of New York in 1860.

An Editor's Vacation.—The editor of a French contemporary announces to his readers that he is going to take a two months' leave of absence, in order to relieve them of his writings and himself of a stone in the bladder.

A Law that Should be Observed.—It is stated in the *Sun* that there is in New York a city ordinance which provides that no person shall place or post or cause to be placed or posted in any street of the city "any handbill or advertisement giving notice of any person having, or professing to have, skill in the treatment or curing of any illness, or offering for sale any medicine, under a penalty of \$25." It is a pity that this ordinance is not enforced.

The Rays Did Not Depilate.—A man in Paris heard of a case in which the hair of the head fell out from a patch exposed to the x-rays, and thought he had discovered a way to make his fortune. He accordingly advertised that he would guarantee to remove the mustaches and whiskers with which some French women are adorned. He took his fees and exposed the patients to the apparatus, but, as the hair showed no sign of disappearing, he was straightway arrested for fraud.

Tenement Houses in Greater New York.—In the proposed charter for Greater New York it is required that all tenement houses must have light, ventilation, and ample means of exit in their construction. They are to be inspected twice each year, and the infected and uninhabitable buildings must be condemned. Two buildings cannot be placed on the same lot, unless there is a clear open space between them, not less than ten feet wide. No building shall occupy more than sixty-five per cent. of the area of its lot. In tenement houses erected after June 16, 1897, every sleeping-room must have a window, at least twelve square feet in size, admitting light and air directly from the street or yard.

Pennsylvania and Maryland Union Medical Association.—The nineteenth annual session of the Pennsylvania and Maryland Union Medical Association was held at York, Pa., on August 27th. An address of welcome was delivered by Dr. T. M. Livingston, of Columbia, president of the association, and was responded to by Dr. Charles G. Hill, of Baltimore. Addresses were delivered also by Drs. Joseph Price, of Philadelphia, and E. W. Meisenhelder, of York. The following officers were elected for the ensuing year: *President*, Dr. Joseph Price, of Philadelphia; *Vice-Presidents*, Drs. C. A. Rahter, of Harrisburg; Charles G. Hill, of Baltimore; *Secretary and Treasurer*, Dr. Roland Jessop, of York; *Executive Committee*, Drs. Alexander R. Craig, of Columbia; A. A. Long, of York; G. H. Bare, of Cecil County, Md.; G. H. Rohé, of Baltimore; W. M. Weidman, of Reading; S. D. Risley, of Philadelphia; George R. Welchans, of Lancaster; C. G. Treichler, of Honeybrook; and H. L. Orth, of Harrisburg.

A Physician's Right to Withhold Alcohol.—It is stated in the *British Medical Journal* that the highest criminal court in Magdeburg, on May 28th last, gave

judgment in a trial, at the instance of the State attorney, of Dr. Hirschfeld, who was accused of having caused or accelerated the death of a man who had been thirty-six hours under his care whom he had sent to hospital, where, after treatment for eight days with large doses of alcohol and quinine, the patient died. The accused had administered no alcohol. The disease was stated to have been serous inflammation of the cellular tissue of the left arm, ushered in by pyrexia (blood poisoning). The district medical officer and one of the hospital staff attributed the death to the withholding of alcohol. In justification, Dr. Hirschfeld pleaded that he believed alcohol to be mischievous in all diseases, taking away the patient's strength. Smith, of Marbach, quoted Harnack, of Halle, and Drysdale, of London, and there were two adjournments to procure an authoritative opinion from the General Medical Council of Saxony, which opinion called attention to the great change of medical opinion as to the therapeutic value of alcohol, and upheld the principle that it is inadmissible to put any limit to the exercise of the individual judgment of the physician. There was a verdict of acquittal, and the State was made liable for the costs of the prosecution.

"**Janus**" is the name of a new international bi-monthly periodical to be devoted to the history of medicine and to medical geography. The new journal is published in Amsterdam under the editorial charge of Dr. H. F. A. Peypers. Among the list of associate editors appear the names of the following Americans: Surgeon-General Dr. George M. Sternberg, of the United States army; Dr. William Osler, of Baltimore; and Dr. William Pepper, of Philadelphia. In the list of collaborators are Dr. L. C. Gray, of New York; Dr. J. Guitéras, of Philadelphia; Dr. A. Jacobi, of New York; Dr. Charles Jewett, of Brooklyn; Dr. L. C. Lane, of San Francisco; Dr. A. E. Regensburger, of San Francisco; Dr. N. Senn, of Chicago; Dr. F. A. Shattuck, of Boston; Dr. J. T. Whittaker, of Cincinnati; and Dr. Charles Denison, of Denver. The first number, that of July–August, 1896, opens with an introduction in French, entitled "*Janus Redivivus*," by Prof. B. J. Stokvis, of Amsterdam. This is followed by articles on "*Variolation and Vaccination*," by Dr. J. Petersen, of Copenhagen; "*Study of Leprosy in Iceland*," by Dr. E. Ehlers, of Copenhagen; "*History of the Functions of the Cerebral Cortex*," by Professor Adamkiewicz, of Vienna; "*Vaccination against Snake-Poison*," by Dr. Calmette, of Lille; "*The Early History of Lanolin*," by Professor Husemann, of Göttingen; "*History of Diphtheria in Denmark*," by Dr. J. Carlsen, of Copenhagen; "*A Pseudo-Precursor of Pasteur*," by the editor, Dr. Peypers; and the "*Medical Jurist of Three Centuries Ago*," by Dr. R. Landau, of Frankenberg. These articles are written in English, French, or German, according to the nationality or inclination of the authors. The number closes with a number of abstracts on subjects relating to medical geography and the history of medicine. If the promise of the first number is fulfilled, *Janus* will be a very valuable addition to medical periodical literature.

Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEEDMAN, M.D., New York City. In Twenty Volumes. Volume VIII. "Diseases of the Digestive Organs." New York: William Wood and Company. 1896.

THE publishers announce that they have again been obliged to issue a volume of this series out of the regular order, and that the seventh volume will be the next to appear. The surprising thing is, not that a volume must occasionally be published ahead of its turn, but that one appears with such regularity every three months. When it is remembered that the contributors to this work are scattered far and wide over the world, and that each doubtless writes in his own language and must be translated, we can only marvel at the success of the editor and publishers in keeping their promise of four volumes a year.

The present volume deals with the "Diseases of the Digestive Organs." The first article, that on "Diseases of the Mouth," by Professor Mickulicz and Dr. Kümmel, of Breslau, treats of the general diseases of this cavity, and is an excellent presentation of the subject. We find little said of the local affections of the tongue, lips, and other parts, and we presume that these are to be treated of in a subsequent volume. Following this is a short but sufficiently comprehensive article by Dr. R. H. Fitz, on "Diseases of the Esophagus," and this is succeeded by one of considerable length on the "Diseases of the Stomach," written by Dr. Max Einhorn. The author devotes a number of pages to a consideration of the various manipulations employed in the examination of the stomach and in the treatment of its disorders, the explanation being accompanied by numerous well-made illustrations, which are apparently original. Professor Leo, of Bonn, has an article of about thirty pages on the "Diseases of the Pancreas." If the aim of study is to learn that we know nothing, this article admirably accomplishes the object, for one rises from its perusal with the conviction that most pancreatic affections can be diagnosed only in the dead-house, or if, perchance, diagnosed earlier, nothing can keep the sufferers from this place. This is followed by a well-written and very original article on the "Diseases of the Peritoneum;" that is to say, on peritonitis from various causes. The section on "Appendicitis" is interesting and instructive. The author, Dr. B. F. Curtis, of New York, being a surgeon, is naturally inclined to the operative side of the present controversy, yet he is by no means intemperate in his advocacy of surgical measures. Not only this section but the whole article may be read with profit by physician and surgeon, alike. The concluding articles in the volume are on "Animal Parasites" and "Treatment of the Diseases caused by Animal Parasites" the first by Dr. J. Ch. Huber, of Memmingen, in Bavaria, and the second by Dr. James M. French, of Cincinnati. The first article is very rich in bibliographical references and a little too academic for the average physician, we imagine, yet it appears to be exhaustive in its treatment of the subject. The second article, that on treatment, is thoroughly practical. The volume, regarded as a whole, appears to be fully up to the high standard set by the earlier numbers of the series, and it becomes more and more evident that the promise of an authoritative work on latter-day medicine will be kept.

THE FUNDUS OCULI, WITH AN OPHTHALMOSCOPIC ATLAS ILLUSTRATING ITS PHYSIOLOGICAL AND PATHOLOGICAL CONDITIONS. By W. ADAMS FROST, F.R.C.S., Ophthalmic Surgeon, St. George's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital. New York: Macmillan & Co. Price, \$18.

THIS publication, which forms a book nine and a half by twelve inches and is one and a half inches thick, is printed in large (Columbian) type on heavy white paper. The text of the work is preceded by a preface, table of contents, list of illustrations, and an introduction. There are forty-six figures in the body of the text and forty-seven plates of chromolithographs with one hundred and seven figures, which represent all of the more common appearances of the fundus oculi in health and in disease. All of the colored plates were produced from drawings from actual cases, made by an artist

under the direct supervision of the author. The upright image and artificial light were employed, except in a few instances, in which the indirect method was used. In the introduction an argument is advanced for the purpose of impressing the general practitioner with the importance of a knowledge of ophthalmoscopy, and the work is avowedly produced for his use. Ophthalmoscopy cannot be practised satisfactorily by those who employ it only occasionally; for this reason such publications as the one under review will be consulted most frequently by the student in ophthalmology. The text of the work, which occupies two hundred and eight pages, is divided into thirteen chapters, which are devoted to the discussion of the anatomy of the parts involved in the production of the fundus picture, explanations of the different appearances observed, etiology, and normal and pathological histology. The discussion of the different conditions observed in the fundus bears evidence of very careful observation and research. It is fully up to date, except in some parts relating to the anatomy of the retina, where the most recent views have not been adopted, and in some minor details of morbid anatomy, particularly in regard to albuminuric retinitis. The direct, concise, and lucid manner in which the descriptions of the various conditions are given is truly admirable. Exhaustive without being verbose, complete in facts without being confusing, the conception and completion of the argument leaves little to be desired. Too much cannot be said in praise of the colored plates. They faithfully represent the conditions that they are intended to depict, producing the best impression when viewed by artificial light. Seven plates—twenty-one figures—are devoted to the representation of physiological variations in the appearance of the fundus. This is an excellent departure, since it serves to acquaint the student with the great variations in physiological conditions—a point often insufficiently emphasized. Plates representing the appearances of the fundus when intra-ocular growths, tubercle, or entozoa are present have been omitted, but, on account of their relatively rare presence, this omission does not detract greatly from the value of the work.

A MANUAL OF ANATOMY. By IRVING S. HAYNES, Ph.B., M.D., Adjunct Professor and Demonstrator of Anatomy in the Medical Department of the New York University; Visiting Surgeon to the Harlem Hospital. Philadelphia: W. B. Saunders. 1896.

THIS is the work of a practical instructor, one who knows by experience the requirements of the average student and is able to meet these requirements in a very satisfactory way. It is a book on regional and topographical anatomy chiefly, a large part of it being devoted to a description of the abdominal and thoracic viscera and their relations to the surface of the body. The illustrations are largely reproductive of photographs of dissections, and many of them are excellent. The author has endeavored to depict the relation of the viscera to the surface landmarks by means of composite photographs, but not with great success, for, like all composite photographs, they are quite indistinct. The author calls special attention in his preface to the index, and a careful testing of it convinces us that he has cause to feel satisfied with it. The book is one that can be commended.

DIAGNOSIS AND TREATMENT OF THE RECTUM, ANUS, AND CONTIGUOUS TEXTURES. Designed for Practitioners and Students. By S. G. GANT, M.D., Professor of Diseases of the Rectum and Anus, University and Woman's Medical Colleges; Lecturer on Intestinal Diseases in the Scarlett Training-School for Nurses, etc., Kansas City. With two chapters on "Cancer" and "Colotomy" by HERBERT WILLIAM ALLINGHAM, F.R.C.S. Eng., Surgeon to the Great Northern Hospital, etc. Illustrated with 16 full-page chromolithographic plates and 115 wood engravings in the text. Philadelphia: The F. A. Davis Company. 1896.

IF it is true, as has many times been stated, that doctors want picture books, then the volume just issued will meet a good sale. We are inclined to believe, however, that American physicians are being educated up to a standard of illustration which the present work has failed to reach. In the abundance of woodcuts and colored drawings, mediocrity rather than finished elegance and accuracy of detail has prevailed. The author has aimed to give to the physician seeking knowledge of these ailments and the methods advo-

ated for their relief a practical working book, and with this aim has scattered his object lessons with a profuse bounty.

It is unfortunate that the printer did not insert tissue slips to face the lithographs, and thus prevent sticking of the text page, as happened in several instances in the volume before us. The text shows a wide familiarity with these diseases, and methods of cure and authorities are frequently quoted. "Railroading as an Etiological Factor in Rectal Diseases" is a chapter not to be found in other similar works. The author's railroad-hospital work and society connections have evidently made his subject familiar to him.

The work is eminently practical, and gives the impression of honesty of opinion as the result of honest search for truth.

THE NON-HEREDITY OF INEBRIETY. By LESLIE E. KEELEY, M.D., LL.D. Chicago: S. C. Griggs & Co. 1896.

THIRTY-NINE chapters, comprised within three hundred and forty-two pages, and covering all forms of questions bearing upon the general subject of inebriety, have the ultimate aim of demonstration that it is a disease, not of hereditary origin, but one readily curable. The author states that in the discovery of his method of cure he investigated the question on the lines of natural selections relating to pathology. "I learned," he says, "that cells acquire an immunity from poisons by being poisoned. I finally learned that certain well-known drugs will obliterate the vestiges of variation, or whatever changes there may be in nerve cells after long use of alcohol."

Just what these drugs are is not mentioned.

HAHNEMANN'S DEFENSE OF THE ORGANON OF RATIONAL MEDICINE, and of his Previous Homœopathic Works against the Attack of Professor Hecker. An Explanatory commentary on the Homœopathic System. Translated by R. E. Dudgeon, M.D. Philadelphia: Boencke & Tafel. 1896.

THIS work has not hitherto been translated. It was supposed to have been written by Friedrich Hahnemann, son of the father of this system of medicine, but the translator believes it to be in reality the work of the paternal master hand. The reply was made at a time when homœopathy was threatened with overthrow from the attacks of Hecker, of Dresden, who at that time was a leading authority. This is said to be the only writing extant in which Hahnemann defends his teachings, and will consequently be read with interest by all interested in them. It is not a purely defensive work, as occasional thrusts at the scientific medicine of the day are found here and there, and the translator has left all of the asperities of diction for which the writer was occasionally noted.

A letter from Hahnemann himself to his publisher will be found interesting. As to whether it was worth while to translate the "refutation," we must leave the reader to decide.

BLIND LEADERS OF THE BLIND: The Romance of a Blind Lawyer. By JAMES R. COCKE, M.D., author of "Hypnotism," etc. Boston: Lee & Shepard. 1896.

THERE are no less than fifty-two chapters in this novel. Most of them are devoid of interest or of sufficient literary newsworthiness to explain their existence.

AN INQUIRY INTO THE DIFFICULTIES ENCOUNTERED IN REDUCTION OF DISLOCATIONS OF THE HIP. By OSCAR H. ALLIS, M.D., Surgeon to the Presbyterian Hospital, Philadelphia, etc. The Samuel D. Gross Prize Essay. Philadelphia. 1896.

AFTER some twelve pages of interesting reminiscences, the essay takes the form of a discussion of the following propositions:

1. The capsule is the most important agent against traumatic dislocations of the femur.
2. For the laceration of the capsule and dislodgement of the head of the femur, the femur is employed as a lever.
3. Every lever has a fulcrum; the fulcra required in dislocations of the femur are bony and ligamentous.
4. Dislocation by thrust, if possible, is infrequent.
5. Reduction by circumduction is the simplest, the most brilliant, and the most hazardous of all modes of replacement.
6. Methods suggested for reduction of dislocation of the head of the femur when associated with fracture of the shaft.

An introductory study treats of the anatomy of the parts; then the lesions produced in experimental work are taken up, and this is followed by pathological considerations. In Part II, reduction of dislocations by manipulation is fully entered into and the methods and obstacles are critically examined. The illustrations are numerous and instructive, and the whole essay is deserving of much praise.

ELEMENTARY ANATOMY AND SURGERY FOR NURSES. A Series of Lectures Delivered to the Nursing Staff of the West London Hospital. By W. MCADAM ECCLES, M.S. Lond., F.R.C.S. Eng., Assistant Surgeon to the West London Hospital, Assistant Surgeon to the City of London Truss Society, etc. London: The Scientific Press, Limited. 1896.

THE more important points in anatomy requisite for a nurse to know are particularly brought out. An abstract of surgery is given in much the same manner. These are important matters, especially for surgical nurses, to acquire, and have not always been dwelt upon in works upon nursing.

There are nearly one hundred illustrations.

Perhaps most of the information could be obtained from other works usually found in the library of the trained nurse, but here the essential points are given in compact form.

ENCYKLOPÄDIE DER THERAPIE. Herausgegeben von OSCAR LIEBREICH, Dr. Med., Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universität, unter Mitwirkung von MARTIN MENDELSON, Dr. Med., Privatdocent der inneren Medicin an der Friedrich-Wilhelms-Universität, und ARTHUR WÜRZBURG, Dr. Med., Kgl. Sanitätsrath, Bibliothekar im Kaiserlichen Gesundheitsamte. Erster Band, III. Abtheilung. Berlin: August Hirschwald. 1896.

THIS part of Liebreich's "Cyclopedia of Therapeutics" completes Vol. I. It includes titles from Ceradial to Diamine, and contains such important subjects as cinchona, and its alkaloids, chloral, chloroform, chlorosis, cholera, cocaine, cystitis, intestinal affections (under Darm), and diabetes. The articles are concise but comprehensive, and contain all the information needed for the average reader, expressed in the fewest possible words. A feature of the work is a brief notice of all the health resorts in the world. Among them we find: "Coney Island, Ort im Staate New York, Seebad." As a work of reference for the busy practitioner, this one leaves nothing to be desired.

TRANSACTIONS OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS, HELD IN WASHINGTON, D.C., September 5, 6, 7, and 8, 1893. In two parts. Washington: Government Printing Office. 1895.

THAT it required two volumes of over eleven hundred pages each of small-type print to contain the papers and discussions indicates what a vast amount of work was represented in this first congress of the Americas.

That such a meeting and exchange of views can only be enhanced in its benefits by a distribution of the published transactions goes without saying. Much can be learned by physicians of North America concerning the diseases peculiar to the southern climes by the study of these papers; the converse is probably of equal truth. The papers are not uniformly of the highest scientific order, and it would be unjust to medical America to have the impression go abroad that these two volumes represent the best effort of scientific medical thought on this side the Atlantic.

TRAITEMENT DES MALADIES DES FEMMES PAR L'ÉLECTRICITÉ. Par le DR. L. R. REGNIER. With preface by DR. LABADIE. Paris: Lagrange. 1896.

FOR all those whose interests lead them toward the study and employment of the powerful therapeutic agent, electricity, in gynecology, Dr. Regnier's work will prove instructive. The literature has been carefully worked over, and the author's personal experience has been brought to bear upon the selection of data and commentation. This is one of the *Progrès Médical* series of publications.

ANLEITENDE VORLESUNGEN FÜR DEN OPERATIONS-CURSUS AN DER LEICHE. Von PROF. E. VON BERGMANN und DR. H. ROCHS. Third enlarged edition, with 63 illustrations. Berlin: August Hirschwald. 1896.

THIS is a very useful little work, well illustrated, and adapted for the use of students of operative surgery, and might be of

aid likewise to teachers of this branch as well as that of regional anatomy.

It is arranged in the form of fifteen lectures upon operations on the cadaver.

FEAR. By ANGELO MOSSO. Translated from the Fifth Edition of the Italian, by E. LOUGH and F. KIESOW. London, New York, and Bombay: Longmans, Green & Co. 1896.

THIS is a work in which physicians will find much of interest. There are chapters on the circulation of the blood in the brain during emotion, trembling, the physiognomy of pain, fear in children, maladies producing fear, hereditary transmission, etc. The author believes that fear is a disease to be cured.

A HANDBOOK ON LEPROSY. By S. P. IMPEY, M.D., M.C. Late Chief and Medical Superintendent, Robben Island Leper and Lunatic Asylum, Cape Colony, South Africa. Philadelphia: P. Blakiston, Son & Co. 1896.

COMING from one experienced at one of the largest leper settlements in the world, the little work of Dr. Impey should carry some weight with it. It is profusely illustrated and well calculated to meet the want for which it was especially written, *i.e.*, to supply information to medical men as well as to interested laymen upon the subject of what leprosy is and what it is not. The author's experience at the Robben Island Infirmary taught him that many cases were sent in as leprosy which were in reality something entirely different.

DIE HEILUNG DER SYPHILIS. Von DR. C. WESTERFIELD. Wiesbaden.

A LITTLE brochure intended for the patient, giving him useful instruction, not alone about the care necessary in bringing about his own cure, but also concerning the precautions necessary to prevent danger to others. There has been too little effort on the part of physicians to instruct the public in those things which should be known about syphilis.

It may be that such literature is not put forth with wholly unselfish motives, but if accidental transmission is prevented in a few instances the end may justify the intention.

FORMULAIRE. Aide-Mémoire de la Faculté de Médecine et des Médecins des Hôpitaux de Paris. Par le DR. FERDINAND ROUX, Mention Honorable de l'Institut, etc. Fourth Edition. G. Steinheil, Editor. Paris. 1896.

ALPHABETICALLY arranged as eight subjects, with the first four letters at the top of the page, in dictionary fashion, to make reference easy, and giving the various plans of treatment under the names of the different authorities. Dr. Roux's little work comprises in its four hundred and twenty-three pages much therapeutic information in a compact and accessible form. The paper and print are good, but the binding is of rather thin cardboard.

DIE PATHOLOGIE DER SCHUTZPOCKEN IMPFUNG. Von S.-R. DR. L. FÜRST, Special-Arzt für Kinderheilkunde. Berlin: Verlag von Oscar Coblentz. 1896.

COMING, as this work does, just as we are celebrating Jenner's centennial, it seems very timely. The author has considered preventive vaccination from its many sides, and has devoted much space to the abnormal and pathological appearances which follow now and then, and has pointed out the proper therapeutic measures to pursue in these conditions. These are grouped under the different headings: "Auto-inoculation," "Abnormal Local Course," and "Generalized Anomalies." Under the head of infections are given first at some length the various dermatoses, and secondly, the other infectious processes. Ten pages of literary references close a volume which will prove of interest to a large class of readers, including the dermatologists.

AFFECTIONS CHIRURGICALES DU TRONC (RACHIS, THORAX, ABDOMEN, BASSIN), STATISTIQUE ET OBSERVATIONS. Par le DR. POLAILLON, Chirurgien de l'Hôtel Dieu, etc. Paris: Librairie Octave Doin. 1896.

THE author, already known by his hospital statistics of surgical affections of the extremities, presents in this volume the statistics of his hospital experience, extracting the principal facts of importance, and giving the results of treatment with and without operation. The fatal cases have not been omitted and often teach useful lessons. Such a work, based upon personal observations extending over a period of

seventeen years, carries with it an element often lacking in compilations giving the experience and opinions of a number of different observers.

Part First treats of the various diseases of the thorax, abdomen, pelvis, and spinal column; Part Second will comprise those of the ano-rectal and genital regions.

Most of the histories of cases are given with great detail, with temperatures and changes from day to day.

TEXT-BOOK OF COMPARATIVE ANATOMY. By ARNOLD LANG, Professor of Zoology in the University of Zurich, formerly Ritter Professor of Phylogeny in the University of Jena. Translated into English by HENRY M. BERNARD, M.A. Cantab., and MATILDA BERNARD. Part II. London and New York: Macmillan & Co. 1896.

THIS volume corresponds to the third and fourth parts of the original, which were late in appearing, and the difficulties of translation have combined to cause a delay in the appearance of this second volume of Professor Lang's comparative anatomy of the invertebrata. In spite of this delay, zoologists will be repaid in the knowledge that the material has been well worked over before being submitted to the printer. The drawings, which are numerous, have been almost wholly the work of the author's pen. The translation is commendable, when the difficulties of such an undertaking are considered.

The volume is in reality more in the nature of a comprehensive treatise upon the groups with which it deals, "Mollusca," "Echinodermata," and "Enteropneusta," than an unbroken continuation of the first volume.

HOW TO FEED CHILDREN. A Manual for Mothers, Nurses, and Physicians. By LOUISE E. HOGAN. Philadelphia: J. B. Lippincott Company. 1896.

THIS is a work based upon various papers which have appeared of late in periodical literature. It offers in a practical form suggestions as to diet in infancy and childhood, such as are approved by the best authorities. There are two hundred and thirty-six pages, inclusive of index, and all worth reading. Much valuable information is given upon this important topic.

BRAITHWAITE'S RETROSPECT OF MEDICINE. Volume CXIII. January 7th to June, 1896. London: Simpkin, Marshall, Hamilton, Kent & Co. 1896.

THIS half-yearly journal contains its usual retrospective view of discoveries, practical improvements, and advances in all departments of medical science.

A general index covering the volumes issued since 1893 is contained in this number, providing easy reference to any subject one may be investigating.

DES ANGINES COUENNEUSES NON-DIPHTHÉRIQUES. Considerations sur la Pathogénie, le Diagnostic, et le Traitement. Par M. le DOCTEUR DUFAUD, Médecin-Major de 2^d Classe. Paris: A. Maloine, Editeur. 1896.

A BROCHURE of a hundred and odd pages covering the various forms of membranous affections of the throat which are not due to diphtheritic infections. Twenty-eight observations are given and a bibliographic index is appended.

The question is an important and interesting one, and every light that can be thrown upon it is welcome.

VERÖFFENTLICHUNGEN AUS DEM GEBIETE DES MILITÄR-SANITÄTSWESENS. Herausgegeben von der Medicinal-Abtheilung des Königlich Preussischen Kriegsministeriums. Heft 10. Berlin: Verlag von August Hirschwald. 1896.

THIS volume is taken up chiefly with a consideration of the x-rays, and contains numerous excellent examples of shadow-picture pathology.

ON GERMINAL SELECTION. By AUGUST WEISMANN. Chicago: The Open Court Publishing Company. 1896.

THIS is a translation by J. T. McCormack from an address delivered before the International Congress of Zoologists at Leyden, September 16, 1895.

The author, while assuming that primary variations are accidental, endeavors to demonstrate that an interior mechanism exists which compels them to go on increasing in definite direction the moment selection intervenes.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 13, 1896.

JOHN SLADE ELY, M.D., PRESIDENT.

A New Method of Preparing the Blood for Clinical Purposes.—DR. LOUIS WALDSTEIN said that since the work of Ehrlich and his followers, attention had been drawn again to the granules that are found in leucocytes, of which Max Schultz gave a description long before the studies of Ehrlich on this subject. Since that time the examination of blood with a view of determining the nature and the number of these granules had entered the clinical field and had become more important as a diagnostic method.

The method of Ehrlich and his followers was more especially one that could be applied in the laboratory only, as it required certain special apparatus and considerable time was needed to perfect the coloring. A number of other investigators had, however, given their attention to this clinical method, among others, Hardy and Kanthack in England, several investigators in Germany, and Dr. Ewing in this country. Dr. Ewing had originated a method which came very near to the ideal one. During last year, the speaker said, he had devoted considerable attention to this subject, and in the *Berliner klinische Wochenschrift* of April of last year he had published the description of a method which, with some modifications, he desired to describe and demonstrate this evening. All the various methods had for their principal object the rapid and perfect fixation of the blood. The more perfectly and the more quickly this was done, the better. Heat, when applied in various ways, did this in more or less complete manner; but often the flame and the incubator were not at hand at the bedside, and hence he had resorted to the fumes of osmic acid. He had used this agent previously in some studies that he had made under Hanvier, in Paris, in 1881. But there was a disadvantage connected with this plan, *i.e.*, the longer the blood was subjected to the fumes of a four-per-cent. solution of osmic acid, the less it would take up of the coloring agent. Last summer, in England, he had made some unsuccessful experiments with formalin, but since that time he had had more encouraging results with this agent. He was now able to prepare a satisfactory slide in six or seven minutes, and this preparation could be kept and examined at leisure. The method was so simple that even the nurse could spread the cover glass for the physician. He believed the time would come when the blood would be examined just as commonly and systematically as the pulse and temperature are at the present time. There was a certain school of pathologists which thought that we had reached the limits of cellular pathology, but he felt confident that the time was coming when cytology would be extended into the profounder study of the blood corpuscle during life, and that here we would find as important information as in the chemical and biological investigations of the serum.

It is most essential that the slides upon which the blood smears are made should be perfectly clean, and it is well to this end to wash them with alcohol and ether, equal parts. The puncture for obtaining the blood is best made with a spear such as is used by the dermatologists for the treatment of acne, for it will then not be necessary to squeeze the finger or ear too much. A fraction of a drop of blood is caught up by the end of a smearing-slip, which is placed at an acute angle on the slide and drawn over its surface with a gentle pressure as soon as the drop has run along the

entire edge of the slip. These slips are made of crown glass, measuring three by two and one-half by one-eighth inches, with edges ground perfectly smooth and rounded. The slide is then immediately placed, blood downward, over the mouth of a bottle containing a ten-per-cent. solution of formalin (twenty-five per cent. of the commercial formalin, which is a forty-per-cent. solution), and allowed to remain there from three to five minutes, which is long enough to fix the blood elements. These specimens can be colored at once or kept any length of time for further treatment. It is advisable to use only Grüber's alcoholic eosin, as the ordinary eosin differs greatly in staining quality as well as in solubility when coming from different factories. For the close study of the two varieties of granules stained with eosin, the best fluid is one containing eosin to saturation in eighty-per-cent. alcohol, to which is added twice the quantity of alcohol of the same strength. The smears are treated with this solution during two minutes, and then washed with water and allowed to dry in the air, and enclosed with Canada balsam, which should not, however, be dissolved in xylol or benzol: that dissolved in cedar oil gave the best results. Besides the large "eosinophile" granules the smaller ones are also distinctly colored; they, as well as the former, are, therefore, "acidophile"—a fact upon which attention had already been called in the above-mentioned article, and which had also been found by Hardy and Kanthack ("oxyphile"). Ehrlich designates them as "neutrophile" granules, because he found that they take up both acid and basic aniline dyes. Although it was not the purpose of this communication to enter upon a discussion of the granules themselves, it might be mentioned that when basic dyes are applied to such specimens previously stained with eosin, these smaller granules take up the basic dye in proportion to the time of exposure to their action; methylin-blue, for instance, will show them violet at first, blue at a later stage, and lastly it will have neutralized the red completely, so that the granules will be entirely discolored. The eosin acts evidently, in respect to the basic dye, as a mordant, much as in the case of cotton in the dyeing industry. Cotton is dyed by an acid color, but not by a basic dye. But if the acid dye be used first, it is found to act as a mordant; the cotton thread is thus provided with what the dyer calls an "acid back." The small acidophile granules also take up what the dyer calls "substantive dyes," just as does cotton. It is possible, therefore, that these so-called neutrophile granules are bodies resembling carbohydrates, and may thus be chemically different from those bodies which take up the basic dyes, *e.g.*, the nucleus and other forms of granules. The large acidophile or eosinophile granules are readily saturated with acid dyes, and will not, therefore, take up any basic dye when once colored with an acid dye, provided that the basic-dye solution employed does not contain above a certain proportion of alcohol when other conditions prevail.

As a basic dye, the speaker said, he used for its distinctive qualities, both with regard to the staining of the nucleus and certain differentiations of the basophile granules, thionin—not the thionin of commerce, but what is also known as the "violet of Lauth." It is also called the thionin of Hoyer, because Hoyer used it in 1890 in his investigations of mucin. The speaker recommends the following staining fluid: a saturated solution of thionin in thirty-three-per-cent. alcohol, to which is added twice the quantity of alcohol of the same strength. The specimens are exposed to this solution for two minutes, thoroughly washed with water, allowed to dry in the air, and enclosed in Canada balsam. Thionin is an excellent nuclear stain, and produces peculiar coloring in certain blood specimens, which are to be treated of on a future occa-

sion; it imparts, for instance, a brownish color to the large granules (basophilic [?]) found in leucocythæmia. Under certain conditions the serum would be of a bluish tinge, and the red discs would be colored from blue to light green, depending upon certain degrees of anæmia. For these reasons this dye was a very valuable one. The best plan was to stain one slide with the eosin and the other with the thionin. That the formalin instantaneously fixed the blood was demonstrated by the fact that in certain cases the "budding" of the leucocytes was well shown.

This solution of thionin is also a capital one-color stain for malaria-blood specimens, the plasmodia appearing with admirable distinctness against the light greenish tinge imparted to the red blood corpuscles.

From a number of indications the speaker ventured to conclude that continuous and systematic examinations of the blood during the entire course of the disease would lead to most interesting results, from which might be ascertained important information not only concerning the action of the toxins in infectious and other acute diseases, but also symptomatic changes in reference to their treatment. He would, therefore, recommend that such blood slides should be made by the attendants quite as regularly as the records are taken of the temperature, pulse, and respiration. At all events, he would continue his work along these lines, and hoped to be able to report upon it at some future time.

DR. JAMES EWING said he had examined a number of specimens stained by this method, and considered it a most excellent one. The method of spreading the blood was in itself a distinct advantage over the ordinary technique, in that the specially ground slide was more easily handled than the cover glass and the blood was spread more uniformly. It seemed to him even superior to the method of dropping the blood on one cover glass and spreading it on another cover glass, for Dr. Waldstein's plan gave a good opportunity for the formation of rouleaux. The fixation he had found to be very simple and in every way satisfactory. He had tried Ehrlich's triacid mixture in addition to Dr. Waldstein's coloring agents, and he had come to the conclusion that the triacid mixture was the best of all. He had found that in the method of fixing by formalin the corpuscles were rather more yellow than when fixed by heat. Ehrlich's dye itself was not a very good nuclear stain, and in specimens fixed by formalin the triacid mixture did not stain so well as when the fixation was secured by heat. The blood plates were, however, rather better stained after the formalin fixation than after heat. The theolin stain was certainly a most valuable one. The whole method called for a very careful and extended trial by every one interested in the study of the blood.

DR. J. S. THACHER asked if the length of time the blood was exposed to the formalin was of importance.

DR. WALDSTEIN replied that he had not found any bad effect from prolonged exposure to formalin, but one or two minutes sufficed for the purpose of fixation.

An Experimental Study of Some of the Nutritional Changes Resulting from Fat Starvation.

—DR. C. A. HERTER presented a paper with this title. He said that this experimental study had been originally undertaken to determine if the lesions of rickets could be produced in growing animals by withholding fats, so far as possible, from their dietary. This was suggested by the fact that the clinical indications of rickets were often made promptly to disappear by the addition of fat to the food. The pig was selected for these experiments.

Pig 1 was experimented upon for a period of fifty-one weeks, beginning December 16, 1893. It was given a limited quantity of milk from the Walker-Gordon laboratory. The average proportion of fat in

this milk was one-fortieth per cent., whereas the milk of the sow usually contains from eight to ten per cent. and that of the cow one per cent. of fat. At the end of the first week, notwithstanding the fact that the animal was receiving about one-three-hundredth part of the normal proportion of fat for a pig, its weight increased, so that at the end of the fifty-one weeks the total increase in weight was sixteen pounds. The animal became markedly constipated, and after a few weeks showed great muscular weakness and the skin and hair became dry. Toward the end of the term of experimentation the animal became very weak and drowsy; then the temperature rose, and it was evident that it was moribund. It was therefore killed. It was found that the hæmoglobin had been reduced to sixty-five per cent., and that there was a slight reduction in the number of red cells. Pig 8 was fed on the same milk, but was allowed to take as much as it desired instead of a limited quantity. At the end of twenty weeks the animal showed some muscular weakness and a tendency to drowsiness. Pig 2 was experimented upon for fifty-six weeks. It was given a supplementary diet of carbohydrates. Toward the end of the experiment the urine was at times saccharine. The fæces were dark and sometimes diarrhœal. The skin remained soft and well nourished. Toward the end slight muscular weakness was noted.

An inquiry into the pathological anatomy of the changes in the skin, principally, showed that there was no subcutaneous fat, but, instead, a layer of gelatinous material. In all the parts of the body where fat was normally located this gelatinous material was found. In Pig 2 some shrinkage was found in the fat cells after eight weeks, and after fourteen weeks they were shrunken to half their normal size. At the end of twenty weeks the fat layer was very pale and the fat cells were reduced in size, but there was no gelatinous material such as was found in Pig 1 and Pig 8. The heart was large, pale, and flabby; there were several hemorrhages on either side of the coronary arteries; instead of the usual fat layer was one of gelatinous material. Many of the muscular fibres of the left ventricle were the seat of slight granular degeneration. The histological appearance of the liver was normal. The kidneys were surrounded by the same gelatinous material, and these organs were enlarged and contained hemorrhagic spots. The epithelium of the tubules everywhere showed granular degeneration, and the cells of the secreting tubes were swollen and degenerating—in short, the kidneys presented the appearance of parenchymatous degeneration. The suprarenals appeared normal, except for being unduly large. The knee-joints were filled with bloody synovial fluid. The cranial bones were thinner and more brittle than normal. The bone marrow was replaced by material having the consistence and appearance of blood clot. Sections from the femur showed normal bone structure. In Pig 2 the femur showed a development of bone almost exactly the same in degree as in Pig 1, the marrow adjacent to the compact bone being very red, while the rest was of the normal pink color. A chemical examination of the gelatinous material showed it to be evidently a phosphorus containing proteid, known as a nucleo-albumin; hence, the process already described might be properly described as a "mucoïd degeneration." An inquiry into the quantity of urea and phosphoric acid and the ratio between the two resulted in showing that there was a very considerable increase in the amount of urea excreted in the course of the experiment; but there was not a corresponding increase in the excretion of phosphoric acid—indeed, there was a slight decrease. The striking feature was the high ratios throughout, or, in other words, the small quantity of phosphoric acid excreted in proportion to the urea. In Pig 9 there was an ir-

regular but slight increase in the phosphoric acid. These animals were fed on fatless milk, and in all the proportion of phosphoric acid was distinctly lower than in the animals fed on normal milk. On feeding Pig 9 with an additional allowance of suet, there was an immediate return to the ratio normally observed in pigs fed on normal diet. This would seem to prove that the low phosphoric-acid secretion was the result of the defective absorption of phosphorus from the intestine. Notwithstanding the great diminution of fat, the quantity of phosphorized fat—the lecithins of the brain—was not diminished. In endeavoring to study minutely this process of mucoid degeneration, it was found that the cells broke up into larger and smaller fat globules; then the cells diminished in size, the cell membrane grew irregular in outline, and in time the cell contents were free from fat. The findings in Pig 2 show that this withdrawal of fat from the milk did not necessarily cause this mucoid degeneration. The chronic degeneration of the kidney in Pig 1 probably resulted from the prolonged activity in excreting nitrogenized material, owing to the highly nitrogenized diet. This view was confirmed by the findings in Pig 2, in which there was much less nitrogenized food, and no such changes were found in the kidney.

The following were the author's conclusions: (1) That the lesions resulting from fat starvation in pigs do not resemble rickets; (2) that prolonged fat starvation leads to the disappearance of fat from the adipose of the body and its replacement by a gelatinous homogeneous-looking substance; (3) that this substance contains a nucleo-albumin but not mucin, but the pathological change may be spoken of for the present as mucoid degeneration; (4) that the lecithins of the brain and liver are not materially reduced by fat starvation; (5) that fat starvation does not lead to mucoid degeneration if the animal be given a large excess of carbohydrate food; and (6) that fat starvation causes a very imperfect absorption of phosphoric acid from the intestine.

DR. ALEXANDER LAMBERT asked if the paralysis appeared to be due to a general weakness or to a nerve lesion.

DR. HERTER replied that he thought it was due to the local atrophy of the muscle fibres. The nerves, however, were not examined.

DR. REGINALD H. SAYRE asked if the hind legs alone were paralyzed in these animals.

DR. HERTER replied that all four legs were affected, but the hind legs suffered more severely in Pig 1. They were about equally affected in Pig 8. As to the question of fat starvation and its bearing on rickets, he would say that the appearances were more like those of scurvy than of rickets. He had examined the breast milk from women nursing rickety children exclusively, and had been surprised to find that in some of these the milk was exceedingly rich in fat, and in none was the fat below the average.

DR. WALDSTEIN said that in a rather large clinical experience he had seen many rickety children, and he had never been impressed with the idea that there was a causal connection between the proportion of fat in the milk and rickets, but he had been impressed with the fact that many children were rachitic whose mothers had been chlorotic or markedly anæmic during the period of pregnancy. He could recall several instances in which the same mother had had both healthy and rachitic children, and in every instance the mother had been anæmic during the time in which she had carried the child which had subsequently developed rickets. He had made many inquiries on this point, with results of a similar tenor. Moreover, he had not found that the use of cod-liver oil was of benefit in rickety children. The only valuable treatment, in his experience, for rachitis, had been the administration

of phosphorus in olive-oil emulsion, according to the method of Kassowitz. He had not obtained such results from the use of Thomson's solution of phosphorus. He recalled having seen in lipomata of old people a gelatinous condition answering the description of mucoid degeneration as given in the paper.

DR. JAMES EWING said he had repeatedly seen the fat about the heart and kidney in cases of acute phthisis replaced by a gelatinous material.

The society then went into executive session.

Clinical Department.

INFLAMMATION OF THE SUBLINGUAL GLANDS.

By A. H. HENDERSON, M.D.,

MONÉ, SOUTH SHAN STATES.

As primary inflammation of the sublingual glands is of rare occurrence, I send the following: On June 2d a Shan came asking me to go and see a woman who was growing a second tongue. I was informed that when this happened they grew very fast and were very sore. I found it to be not a bad description of the general appearance for one who knew nothing of anatomy. The symptoms were those of parotitis—pain, swelling under the jaw, temperature of 100° F., pulse of 120, with a copious flow of saliva, according to the report of the patient, although the amount seemed normal when I saw it. The treatment and subsequent history were those of parotitis. As it seemed to be known by the people, I presume it is not uncommon here, though this is the first case I have seen.

DOES APPENDICITIS FOLLOW FAMILY LINES?

By WILLIAM T. SMITH, M.D.,

HANOVER, N. H.

THREE cases coming under my notice within a few months past have suggested the above question. The following is a brief account of these cases:

CASE I.—A man, forty-five years of age. Acute catarrhal appendicitis. During a year he had had three attacks. The appendix was removed. One year before this operation a daughter of the patient died of peritonitis resulting from appendicitis. She had had three previous attacks.

CASE II.—A child, eleven years of age. I removed a perforated appendix from an abscess cavity. Two weeks before, a first cousin of the patient, twelve years of age, had been operated on in another State for appendicitis.

CASE III.—A boy, aged thirteen. Appendicitis of three days' standing. When he was first seen by me, perforation had taken place and he had general peritonitis. I removed a gangrenous appendix. Just eleven months previously I had made an autopsy on an elder brother of this boy who had died of general peritonitis. I found in his case also a gangrenous appendix.

These are three cases out of about a dozen which I have seen during the year, in most of which no special inquiry was made in the line of the question suggested. Probably the underlying cause of appendicitis is commonly obstruction of the lumen of the organ or of its artery, or of both. Its length, the character of its attachment to the gut, its mobility, its position are important factors in determining obstruction, and such structural characters are doubtless transmitted in families.

PYROZONE AND DILUTE HYDROCHLORIC ACID IN SUPPURATING INFLAMMATIONS OF THE MIDDLE EAR.

By WILLIAM CHEATHAM, A.B., M.D.,

PROFESSOR OF DISEASES OF THE EYE, EAR, THROAT, AND NOSE IN THE LOUISVILLE MEDICAL COLLEGE, ETC., LOUISVILLE, KY.

I SUPPOSE that in giving the history and the result in these cases nothing new is being written. It is my purpose to attract the attention of the physician to the line of treatment that has rendered me the best service in this sometimes most obstinate affection.

CASE I.—A. C.—, male, aged twenty-three years; had had suppuration of the right ear for many years; there was some œdema and tenderness over the mastoid. The discharge from the ear had a very disagreeable odor; there was some discharge through the Eustachian tube into the throat; the auditory canal was much swollen and very tender. Hot applications and hot douches of carbolized water soon reduced the œdema, and gave freer drainage. After partially relieving the stenosis of the auditory canal, with curette and pick I removed large cholesteatomatous masses and found the middle ear and contents swept away, and in its place a large funnel-shaped cavity, base in and apex at about half-way of auditory canal, which at this point was still much contracted. The curette, chromic acid, pyrozone, and many other remedies were used, but the epithelial masses still collected. Formalin, boric acid, and alcohol were tried with the same result.

I finally directed that ten drops of a mixture of dilute hydrochloric acid, gtts. x., and pyrozone, $\frac{5}{8}$ i., be put into the ear morning, noon, and night, after cleansing. A wonderful change was noticed in a few days, and in a short time there was no secretion from the cavity. There has been no return in several months.

CASE II.—Mr. G.— had had suppuration of his right middle ear for twenty years. On cleansing away some inspissated pus I found his case was one of attic disease with bone necrosis. Above the middle-ear cavity proper and not communicating with it was a large cavity, which was filled with inspissated pus and necrosed epithelium. Rough bone was felt with the probe; small pieces were detached with the curette. The ear was directed to be kept thoroughly cleansed by means of carbolized warm water; it was curetted once or twice: iodoform, iodol, boric acid, loretin, formalin, and alcohol were used at different times, with applications of chromic acid and lactic acid; the ear was treated by the dry method also and drained with bits of iodoform gauze, with no permanent relief.

This case was on hand about the same time as the one first reported. The same mixture of dilute hydrochloric acid, gtts. x., in pyrozone, $\frac{5}{8}$ i., was given, with the direction that ten drops be put in the ear one, two, or three times a day, to be left in five minutes after having been forced in deep by firm pressure upon the tragus, and then the ear wiped dry with absorbent cotton. This case in a few weeks began to improve rapidly, going on to recovery with no relapse.

I have treated several similar cases with but one failure, that in a tuberculous subject. Of cases of less severity I have treated many, with only an occasional failure. I have yet to see this treatment fail in acute cases. Of course in the primary stage of acute cases such medication is contraindicated, but after pain, throbbing, and swelling have subsided, and suppuration continues notwithstanding ordinary treatment, the acid and pyrozone check it very promptly.

As to drainage in these cases, the iodoform or some other of the gauzes cut into narrow strips, lately advised by several, has given me by far the best results.

The treatment mentioned is not a cure-all by any

means, but I hope this brief report will lead to others trying the acid-and-pyrozone combination. Of course, when the deeper sinuses are involved surgery is first indicated, then the pyrozone and acid. Under its use I find mastoid-cell involvement much less frequent; I do not believe these effervescing preparations increase such dangers.

TWO CASES OF OBSCURE INTRA-ABDOMINAL LESIONS.

By F. B. TIBBALS, M.D.,

DETROIT, MICH.

THE diagnostic difficulties presented by intra-abdominal lesions are many and varied, and fortunate indeed is the surgeon of experience who escapes error. Many an abdomen has been opened and nothing found to account for existing symptoms; many a cœliotomy has disclosed conditions far different from those previously diagnosed.

When we consider the number of important viscera liable to injury or disease and the obscurity of symptoms pointing thereto, the wonder is that we are not more frequently led astray. From the region of the pancreas, gall bladder, and pylorus to the appendix and viscera of the female pelvis inclusive, lies a surgical field rich in possibilities, teeming with uncertainties and perplexing doubts.

I do not propose in this a clinical paper to cover the diagnostic difficulties of this great surgical field, but by reporting two unusual acute cases to illustrate some of the knotty problems with which any one of us may at any moment be confronted.

CASE I.—Miss Ida S.—, aged twenty, took cold during menses and suffered from dysmenorrhœa, with mild ovarian pain for several weeks following. A bimanual examination disclosed a retroverted uterus, which was considered the cause of the continuance of pain. Ovaries and tubes seemed normal; they were not sensitive on pressure, and I found at no time during this period the slightest rise of temperature. The treatment consisted of the usual uterine sedatives, douches, and rest. I had not seen her for a week, when at 10 A.M., on September 20, 1895, I was called to find her with temperature of 102.5° F. and pulse of 90. She had had a sharp chill the previous evening, and there were great pain and tenderness over McBurney's point. Vaginal examination again disclosed nothing except a retroverted uterus, firm pressure with the vaginal finger eliciting no sensitiveness of right ovary or tube. Dr. Donald Maclean saw her in consultation with me at 4:30 P.M. Temperature then was 104° F.; pulse, 110; pain easier; there was no tympanites and no vomiting. We advised immediate operation, but various delays incident to securing family consent and removal to hospital occurred, and the patient presented a temperature of 105° F. and pulse of 130 when ready for operation at midnight.

The abdominal incision was made adjacent to the appendix, but the appendix was found to be normal. Further examination disclosed a broken-down right ovary, the abscess cavity capable of holding perhaps one-half drachm. This unexpected abscess had undoubtedly ruptured at the inception of the attack and already had induced localized septic peritonitis.

Both tubes were found swollen (catarrhal, without pus) and were removed with some difficulty through the original incision.

The abdomen was thoroughly flushed and drained, but the peritonitis extended and the patient died twenty-eight hours later.

CASE II.—Mr. J. C. W.—, aged thirty-five, was riding his wheel between 5 and 6 P.M., Saturday,

April 25, 1896. He threw himself off in order to escape an approaching electric car and struck the asphalt pavement with some force, the gluteal region being the impinging part. He thought himself uninjured and remounting his wheel rode five miles, then went home, ate a hearty supper, and took a young lady out to an evening entertainment. After escorting her home, while riding down town on the wheel, he for the first time felt abdominal pains, which soon so increased in intensity that he sought relief in a convenient drug store, where I was called to see him at 12:30 A.M., seven hours after his fall. He attached no importance to his fall, and, as the only objective symptom was pain, I gave him anodynes, took him home in a coupé, and left him resting easily.

Sunday, 10 A.M.—Had a restless night. Little pain, but great soreness. A full breath was painful. There was no vomiting. The patient had urinated; temperature, 99° F.; pulse, 90.

5 P.M.—Bowels had not moved nor had gas passed since the morning visit, though he had taken calomel, gr. iij., and phosphate of sodium, $\bar{5}$ i. Temperature was now 100° F.; pulse, 120. Tympanites beginning.

I secured Dr. Maclean in consultation two hours later. Temperature was now 101.5° F.; pulse, 130; tympanites more marked. Four ounces of clear urine were drawn by catheter, being the entire quantity secreted since 9 A.M. The rapidly developing tympanites, rising temperature and pulse, and paresis of the intestinal tract were considered indicative of some unusual intra-abdominal lesion and immediate operation was proposed and accepted.

Operation was performed at 9:30 P.M. with Dr. B. P. Brodie as anæsthetist. A three-inch incision was made below the umbilicus and the accessible viscera were carefully examined, but neither hernia, volvulus, intussusception, nor hemorrhage was found. The intestines were congested and much distended with gas, and there was much free fluid in the abdominal cavity. The incision was now extended upward, the bowels were turned out, and careful search was made for a point of rupture. At last on the posterior wall of the stomach close to the pylorus was found a raw surface, the result of ruptured adhesions, and a small hole extending completely through the stomach wall, through which the contents of the stomach were oozing. The point of rupture was the site of an old ulcer, of which neither the patient nor his family could give any history, and the concomitant adhesions to the duodenal mesentery when torn loose by the jolt of his fall made a rupture of the weakened stomach wall possible.

The wound was carefully repaired, the cavity thoroughly douched, and the long incision rapidly closed. The patient rallied well and apparently would have recovered but for an unsuspected abnormality of the kidney, to which I attribute his complete suppression of urine, for no urine whatever was secreted from the catheterization two and a half hours before operation until his death at 5 P.M. the next day.

The post-mortem revealed a congested right kidney normal in size, while the left kidney was only one-fourth its usual size and was firmly embedded in the median line against the head of the sacrum. This abnormality is of interest both as such and as a factor in the final outcome of the case. Evidently the one kidney capable of secreting became inactive from shock and thus deprived the patient of otherwise good prospects of recovery. The condition of the stomach and intestines post-mortem was excellent, the congestion and distention of intestines and all evidences of peritonitis having disappeared, while the hole in the stomach was completely healed.

These two cases met with in my practice during the year past seem to me worthy of record as illustrative of the diagnostic difficulties of intra-abdominal lesions.

Primary abscess of the ovary is a condition of extreme rarity and one which we can seldom recognize during life. In my case diagnosis was not possible until the rupture of the abscess, when exact diagnosis became of little moment, as the rapidly developing symptoms made clear the need of prompt operative interference.

The other case is remarkable in that a deep ulcer of the stomach had existed and extensive adhesions had formed without the knowledge of the patient, and because so slight an injury as the jolt of a fall upon the buttocks cost him his life.

My thanks are due to Dr. Maclean for the skill, unfortunately unavailing, with which he wielded the knife, as well as for his valuable diagnostic assistance.

TWO CASES OF HYDROPHOBIA.

By W. MOSER, M.D.,

BROOKLYN, N. Y.

CASE I.—The boy was bitten on the left lower eyelid by a dog. The wound was treated at St. Catharine's Dispensary until completely healed. The Pasteur treatment was not instituted, as the dog, which was a stray cur, was not supposed to be afflicted with rabies. Seven weeks after the date of the bite the boy was admitted into St. Catharine's Hospital, service of Dr. Moitrier, with the following symptoms: Great muscular prostration, great excitability, difficulty in swallowing, especially water. There was no fear of water (hydrophobia) *per se*, as the boy could look at a glass of water without showing fear, but as soon as the glass of water was taken from the table and brought to him with the request that he drink it, he would become terror-stricken, falling, if the request for him to drink be urged, into general convulsions. Rectal enemata of water produced no convulsions. Hallucinations occurred at times, the most frequent being that he was being bitten by dogs. Hemiplegia on the injured side was noted. (Edema of the lungs set in on the second day and was the immediate cause of the boy's death. The autopsy, performed by me, showed œdema of the lungs and an acute inflammation of the meninges of the brain and cord. All the other organs were normal, excepting a few punctate hemorrhages on the pons Varolii.

CASE II.—A boy, four years old, was bitten on the left hand by a dog. The wound was cauterized and treated at the boy's home. Five weeks from the date of bite the boy was carried by his father to St. Catharine's Hospital, in the service of Dr. Moitrier. He then presented the following symptoms: great muscular prostration; the difficulty in swallowing water was so great as to cause a peculiar choking sensation at each attempt; hallucinations occurred, the most frequent being that dogs were biting him. The boy had only a few general clonic convulsions. Hemiplegia occurred on the left, the injured side. (Edema of the lungs set in on the second day, to which the boy succumbed.

Remarks.—We note, in reviewing these two cases, the diagnosis of which was confirmed by Drs. Gibier and Labadie, the following peculiarities in their symptomatology:

1. Both boys were under the impression that dogs were biting them.
2. The singular fact that both should have had hemiplegia on the bitten side. Dr. Fuhs concurred in the opinion that the hemiplegia was on the left side.
3. That both boys died in two days from œdema of the lungs.
4. We note the period of incubation—seven weeks in the one case, five in the other.

A POSSIBLE EFFECT OF ANTITOXIN.

BY E. CROSBY CHAMBERLIN, M.D.,

NEW YORK.

WITHOUT discussing the value of diphtheria antitoxin, when early administered, I wish to relate a case which is of some interest. A young woman, aged twenty-two, has been afflicted with a chronic diarrhœa for the past four years. In December I attended her for a gastritis, which after a few washings of the stomach passed away. Two months later diphtheria developed; being pharyngeal at first, it extended in all directions until two days later, when an otitis media with a copious discharge was developed. This day the report from the board of health was received confirming the diagnosis. She had been using for two days corrosive sublimate, both internally and as a gargle. The discharge from her ears by this time was so abundant she could not sleep, it flooding out of the external meatus over the face through absorbent cotton and everything. I at once gave her two grains of antitoxin. The next day the discharge was reduced at least one-half. Later she received another injection of antitoxin, and the following day not only had the discharge entirely disappeared but the diarrhœa was reduced from five or ten stools daily to one or two stools of a normal solid consistency.

That was two months ago and at present she has not had a return of the distressing diarrhœa.

FRACTURE OF THE BASE OF THE SKULL, OF BOTH SUPERIOR MAXILLÆ, OF THE NASAL BONES, OF THE INFERIOR MAXILLA, AND OF THE HYOID BONE — RECOVERY.

BY L. B. SMITH, M.D.,

AND

GEORGE HASLAM, M.D.,

FREMONT, NEB.

On the evening of December 26, 1895, Mr. T. N——, aged sixty-seven, after taking an accustomed dose of a hypnotic, retired to rest and slept until about 2 A.M. of December 27th, in a room upstairs with which he was somewhat unfamiliar, as his habit had been to sleep downstairs. Arising in a semi-conscious condition, as was his wont, to relieve his bladder, he turned as he would have done in his own room below, and in consequence fell down a flight of stairs, a vertical distance of twelve feet, and then rolled or crawled a farther distance of about four feet, where he was found by members of the family, who had been awakened by the noise of his involuntary descent.

Arriving at about 2:30 A.M., I found the patient resting on a lounge, to which he had been carried. He was partially conscious, being able to give an intelligent answer to a direct question and able to complain of pain in the back of the neck whenever his position was changed or when he made an effort to turn. He also complained of pain in the throat. Afterward he had no recollection whatever of this period.

Blood flowed from the mouth and nose; respiration was difficult and could be effected only through the mouth, as the nose was completely closed. The posterior wall of the pharynx was also swollen and tended to increase the difficulty. The left eye was closed, the eyelid blue and much swollen; the right eyelid was swollen and slightly discolored. Pulse was slow and weak.

Further examination demonstrated both superior maxillæ to be separated from the cranium and movable on each other. The nose, which formerly was deflected to the right, was now strongly bent to the left, and the bones were movable. A compound fracture of the lower jaw was discovered on the left side at the posterior border of the canine tooth.

Fractured base of the skull was diagnosed from the condition of the eyes, etc., and was confirmed by further and independent examination made by Dr. Haslam some eight hours later. At this time and later no cause for the pain in the hyoid region could be detected, in spite of repeated examinations made both from within and from without.

On Monday (December 30th) the patient recovered consciousness and at once redoubled his complaints of pain in the throat, especially on making an effort to swallow, no reasonable cause for which could be detected until the tenth day, when he forced a mouthful of fluid down at one gulp. There was an extreme though momentary pain, followed by instant relief. Distinct crepitation in the body of the hyoid was now easy to detect, either on making lateral pressure or when the patient swallowed. Evidently the parts had been firmly held in an unnatural position until now suddenly released.

For two weeks after the accident his gait was unsteady and it was possible to walk only by looking directly in front, a single side glance being sufficient to disturb his equilibrium; to turn a corner was a matter of considerable difficulty. During a period of six weeks he suffered from severe neuralgic pains, which he said shot toward the cranial vertex, and during this whole period it was always necessary for him to support his head with his hands when in any position other than the recumbent. The chest and abdomen were ecchymosed as low as the navel, and were for a long time perfectly black.

Mr. T. N—— made a good recovery, except that in consequence of his refusal to submit to surgical treatment the portions of the lower maxilla are ununited. The roof of the mouth presents a bulging ridge along the intermaxillary suture, where the bones have re-united.

STRANGULATED HERNIA IN AN AGED SUBJECT—OPERATION—RECOVERY.

BY S. S. CARTWRIGHT, M.D.,

ROXBURY, N. Y.

I WAS called, June 23d, to see M. S——, aged seventy-eight, suffering from left inguinal hernia. He had been troubled with it for five or six years. In April last I had reduced it for him and advised him to wear a truss; but he did not follow the advice. On June 24th, after considerable difficulty, I reduced it; but on June 25th it came down again. I then called Dr. A. R. Ellis, of this village, to assist me. We administered ether and kept him under the influence of it for two hours, reducing the hernia, so far as the bowel was concerned; but a portion of the omentum could not be reduced. I saw him again June 25th, and found the hernia strangulated. No further attempt was made at reduction, and we sent for a surgeon, who came but refused to operate on account of the hopelessness of the case. He decided that the omentum and bowel were both gangrenous, which was evidently a mistake. The following day his pulse was between 60 and 70, his temperature about 99° F. I decided that an operation should be performed, and sent for Dr. William Kemble, of Rondout, N. Y. He came on Sunday, June 28th, and after a careful examination it was decided to operate.

The operation was performed by Dr. Kemble, assisted by myself and Dr. Ellis, in the usual manner. On account of hydrocele of the tunica vaginalis testis, it was deemed proper to remove the left testicle. A portion of the omentum was removed, all bleeding vessels were secured by catgut ligatures, the bowel and remainder of the omentum were returned to the cavity of the abdomen, and the wound was closed by contin-

uous suture. The antiseptic used was carbolic acid, 1 to 20.

June 29th.—The patient had rested well. I administered a dose of Epsom salts, which operated in the course of the day.

June 30th.—Temperature, 100.5° F.; pulse, 80.

July 1st.—Temperature, 99.5° F.; pulse, 72. There was no particular pain nor inconvenience. From this time the temperature gradually fell to the normal.

The sutures were allowed to remain until July 10th, when they were removed, the wound being nearly healed. The rubber drainage tube was removed at the same time. On July 12th he was up and dressed.

The surroundings were of the most unpromising kind, and the age of the patient would have led one to expect an untoward result; still the termination was all that could be asked for.

The lesson of this is that we should not despair of such a case if one comes under observation, and instead of waiting for death we should give the patient a chance of life.

SUBPHRENIC ABSCESS.

By L. B. SMITH, M.D.,

AND

GEORGE HASLAM, M.D.,

FREMONT, NEB.

MR. C. R.—, aged forty-five, a man of medium build, of fairly good habits, but who some ten or more years ago would occasionally imbibe too freely, had always enjoyed good health except that some six years ago he suffered from lumbago.

On January 19, 1896, he complained of a sudden severe pain in the right side in the region of the lower ribs. He was compelled to remain two or three days in bed, and then got up fairly well. During the week following he complained of nothing but weakness and some indefinite stomach symptoms. He was unable to work, but walked around and seemed to be convalescing. He then complained of a neuralgic pain in the left leg, which was diagnosticated and treated as sciatica. The pain disappeared, to reappear on the right side two weeks after its origin in the left side. In each case the limb was somewhat swollen but did not pit on pressure; the veins were slightly engorged but not varicose. After about another week there was pain in the left groin, followed by general abdominal pain. The patient was constipated from the beginning.

On April 21st the pain reappeared in the right side, as at the beginning of the illness, and on the 23d he commenced to vomit and retch, with the eructation of much gas. About the beginning of May the pain became worse and the gastric symptoms more severe. Somewhat later the lower chest began to swell, and subphrenic abscess was now diagnosticated. As soon as this condition was recognized the abscess was opened by Drs. George Haslam and by H. N. Brown, who excised portions of the ninth and tenth ribs and opened the pleural cavity, which was lined with a layer of stratified lymph about five-sixteenths of an inch thick. More than a pint of grumous fluid escaped. The diaphragm was then opened, when a much larger quantity of similar fluid escaped.

On May 19th the patient died. Only a limited post-mortem examination was allowed. It was found that the cavity reached half-way down behind the right kidney. No exciting cause for the condition could be traced.

The Roentgen Rays kill tubercle bacilli, according to a report made to the Académie des Sciences by MM. Lortet and Genoud.

Therapeutic Hints.

Pneumonia.—Calcium chloride in four-grain dose.

Asthma.—Ice pack over pneumogastric in region of neck.—SANGER.

Hiccough.—Sugar. When purely nervous, hydrochlorate of pilocarpine, one-tenth grain, three or four times a day.

Rickets.—

℞ Phosphorus gr. $\frac{1}{100}$.
Cod-liver oil gr. mcccc.
Saccharin gr. lxxv.
Essence of lemon gtt. ij.
M. A small teaspoonful may be taken daily.

—MARFAN, *Revue des Maladies de l'Enfance*, July, 1896.

Gout.—

℞ Magnesii sulph. 3 ij.
Potass. bicarb. gr. xv.
Tr. colchici sem. ℥ x.
Infus. buchu. 3 i.
Ft. haustus. S. To be taken every four or six hours, followed by a large draught of water, not too cold.

—FOTHERGILL.

Granular Conjunctivitis.—

℞ Mercuric oxide gr. iij.
Zinci,
Thymol,
Muriate of cocaine āā gr. ss.
Camphor gr. ss.
Vaseline 3 ij.
M. ft. ung.

—North American Practitioner.

Hypodermatic Treatment of Tuberculosis.—

℞ Beechwood creosote 25 gm.
Camphor 15 gm.
Aristol 10 gm.
Eucalyptol 30 gm.
Sterilized neat-foot oil ad 250 cc.
For hypodermatic injection.

One cubic centimetre (sixteen minims) of this solution contains one-tenth gram (one and one-half grain) of creosote.—V. GILBERT, *Medical Week*.

Creamy Emulsion of Cod-Liver Oil.—

℞ Cod-liver oil 500 parts.
Finely sifted sugar 190 "
Pulv. gum arabic,
Pulv. gum tragacanth āā 5 "
Infusion of coffee 200 "
Rum 100 "

Mix the sugar and gums in a mortar, and in the bottle which is to contain the emulsion shake together the oil and cold infusion of coffee. Pour a sufficient quantity of this liquid into the mortar to make a paste. While stirring, add to the portion remaining in the bottle the rum, and then gradually incorporate it with the emulsion.—*Therapeutic Gazette*.

Night Sweats of Phthisis.—

℞ Liq. potass. arsenit ℥ xv.
Tinct. belladon. ℥ xv.
Aque amygdal. amar 3 v.
M. S. Take from fifteen to twenty drops of the mixture about five o'clock in the evening.

—Pharmaceutische Zeitung.

Irritability of the Bladder after Delivery.—

℞ Salol,
Tincture of hyoscyamus āā 3 ij.
Infusion of buchu q.s. ad 3 vi.
M. S. Teaspoonful three times a day.

—FOTHERGILL, *Manual of Midwifery*.

Migraine.—

- R Pure chloroform, ... āā ʒ ij.
 Alcohol gr. xx.
 Morphine gr. iv.
 Syrup i.
 Water iv.
 M. S. Teaspoonful every half hour till pain is relieved.

—*Journal des Praticiens.*

- R Caffeine citrate gr. xx.
 Phenacetin gr. xxx.
 White sugar gr. xv.

Sufficient for ten capsules. One every three or four hours during the period of the attack.

—*Indian Lancet.*

Diminish the hyperæsthesia of the painful area by a spray of some local anæsthetic, and immediately afterward practise compression of both temporal arteries by means of rings of cork held in place by a gauze bandage. Administer the following in four doses at intervals of two hours:

- R Antipyrin gr. viiiss.
 Sparteine sulphate gr. ʒ/3.
 Caffeine citrate gr. iss.

If there is gastric derangement, the above may be administered by enema.—*ARITZMAN, Presse Médicale.*

Hay Fever.—Discard the use of sprays, and apply to the nostrils, on a cotton pledget, an unguent composed of six parts of cocaine muriate, ten of carbolic acid, twenty of menthol, one hundred and twenty of oil of sweet almonds, two hundred and forty of zinc ointment.—*American Medical Journal.*

Diabetes.—

- R Arsenate of sodium gr. ʒ/8.
 Carbonate of lithium gr. ij.
 Codeine gr. ʒ/8.
 Dry extract of cinchona gr. viij.

Make into one cachet. Prepare thirty such. One after breakfast and one after dinner.

—*ROBIN, Journal des Praticiens.***Flatulent Colic.—**

- R Spirit. chloroformi,
 Tr. cardamomi comp. āā ʒ ij.
 M. S. A teaspoonful every half-hour, in water.

—*BARTHOLOW.*

Quinine Mixture.—The following is advantageous in irritable stomach when quinine is to be given:

- R Sulphate of quinine gr. ij.
 Citric acid gr. vi.
 Simple syrup,
 Syrup of orange flowers āā ʒ ss.

This is to be placed in a wineglass containing bicarbonate of sodium (from three to five grains) in saturated solution, and drunk during effervescence.—*Journal de Médecine de Paris.*

Intestinal Worms.—

- R Oil of chenopodium ʒ ij.
 S. To be given on sugar three times daily, in doses of five drops, to a child of three years, and ten drops to one of ten years. A cathartic should be given every second or third day.

—*C. W. TOWNSEND.*

- R Santonin gr. ij.
 Mild chloride of mercury gr. ss.

M. S. Every night for two or three nights, to a child five or six years old, followed each morning by a purgative dose of castor oil.

—*EUSTACE SMITH.*

To Check Vomiting.—Powdered pimenta, five grains, repeated in ten or fifteen minutes; or pulverized pimenta, five grains, with calomel, one-tenth grain.—*A. S. DOLLOFF, Beverly Farms, Mass.*

Stomatitis in Small Children.—

- R Potassii chlorat. ʒ i.
 Tinct. myrrh. gtt. xx.
 Elixir calisayæ ʒ iiij.
 S. Teaspoonful in water every four hours.

This prescription should not be used if there is present a condition of acute nephritis.—*HARE, Medical Summary.*

Excessive Sweating of the Feet.—

- R Alumol,
 Aristol āā 4 parts.
 Starch 15 "
 Dust into the socks.

—*Therapeutische Wochenschrift.***Dusting Powder for Eczema.—**

- R Pulv. amyli ʒ i.
 Pulv. zinci oxidi ʒ ij.
 Pulv. camphoræ ʒ ss.
 M. S. For external use.

—*HYDE.***Powder for Genital Herpes.—**

- R Powdered alum,
 Powdered starch āā 10 gm.
 M. For external use.

The balano-preputial region is dusted over with this powder. Recovery is usually promptly obtained.—*E. GAUCHER.*

Dyspepsia.—For painful digestion with flatulence:

- R Sodii bromidi 16 parts.
 Pepsini concentrat. 12 "
 Pulv. carb. ligni 8 "
 Aquæ pur. 32 "
 Glycerini 96 "
 M. S. Teaspoonful after each meal.

—*LAMPHEAR, Am. Jour. of Surgery and Gynecology.***Hay Fever.—**

- R Eucalyptol,
 Glycerin āā ʒ i.
 Tinct. opii ʒ ij.
 Aquæ destil. ad ʒ vi.
 S. Use with atomizer three times a day.

—*American Medical Review.***Hemorrhoids.—**

- R Wood tar 3 parts.
 Extract belladonna 3 "
 Glycerin 30 "

- R Magnesia,
 Rhubarb āā 7.50 gm.
 Bicarbonate sodium,
 Carbonate sodium,
 Powd. sugar āā 15 gm.
 Oil peppermint q.s.
 S. Half to one teaspoonful in water two hours after each meal.

—*MAX EINHORN, Medical Weekly.***Erysipelas.—**

- R Tannin 2 parts.
 Camphor 3 "
 Ether 15 "
 S. Paint every hour or two over affected part and adjacent skin.

—*SPERNANDINO.***Chapped Skin.—**

- R Lanolin ʒ iiij.
 Glycerin ʒ iv.
 Boric acid ʒ iss.
 Salol ʒ i.
 Hoffman's anodyne ʒ v.
 Menthol gr. xv.
 Oil of citronella ʒ iiij.

—*Journal des Praticiens, February 22, 1896.*

Alcoholism.—

R Nit. strych. gr. viij.
 Acid. salicylic gr. iv.
 Alcohol i.
 Water iij.
 Make up antiseptically. ℥ xv. = $\frac{1}{8}$ of a grain of strychnine. S. ℥ 15 hypodermically two or three times daily.

—FLINT.

Rheinstadter's Ergot Mixture.—

R Ergotini dialyati spissi. 5 parts.
 Aquæ destillatæ 35 "
 Acidi salicylici 0.1 "
 Glycerini 10 "

A teaspoonful of this mixture, with two tablespoonfuls of lukewarm water, is injected by a rubber-ball syringe into the rectum, after the bowel has been emptied.—SCHAUTA, *Lehrbuch der gesamten Gynäkologie*.

Rectal Alimentation.—

R Cod-liver oil 3 v.
 Yolk of one egg, ...
 Lime water 3 x.
 M. As a nutritive enema.

—*Journal des Praticiens*, March 14, 1896.**Pruritus Vulvæ.**—

R Chloral camph. 3 ij.
 Bismuth subnit. 3 ij.
 Aquæ rosæ 3 iv.
 M. S. Apply to the parts.

Or,

R Argenti nitratis. 3 gr. xx.
 Aquæ 3 i.
 M. S. Paint over the affected parts.

—BARTHOLOW.

Mother's Milk does not quench an infant's thirst. Boiled water should be given freely and with regularity between the nursing periods.

Insomnia of Neurasthenia.—

R Paraldehyde. gr. xxxviij.
 Fluid extract of piscidia gr. lxxv.
 Syrup of wild cherry 3 iss.
 M. S. To be taken at once in a cup of orange-flower water.

—MONIN, *Indépendance Méd.*, July 1st.

Epilepsy.—We read in a foreign exchange that the only remedy of value in epilepsy is bromide of potassium, and the dose should not be stopped for a single day during the period of treatment. Give five grams the first week, six the second, seven the third, and repeat this order. Give bromide so that two-thirds of the dose are taken two or three hours before the customary time for an attack. Always give in a very dilute solution. Small doses of salol combined with the bromide are of value. The patient should not be allowed to sleep during the day. After a year and a half the dose of bromide may be diminished.—*Journal Pract. Med.*

Diagnosis in Laryngeal Disease.—Until Señor Manual Garcia, of London, in 1855, practised successfully auto-laryngoscopy and thus opened the way for Türk and Czerniak, of Vienna, to use successfully the laryngoscope on their patients, aphonia and dysphonia with certain associated symptoms were the only guides to the practitioner in making a diagnosis in laryngeal disease.—DR. MERRICK, *Maryland Medical Journal*.

Headaches from Eye Strain.—Dr. S. Weir Mitchell concludes in an article in the *Medical News*, April 28, 1894, that: 1. There are many headaches which are due directly to disorders of the refractive or accommodative apparatus of the eyes. 2. In some instances the brain symptom is often the most prominent and sometimes the sole prominent symptom of the eye troubles, so that, while there may be no pain or sense of fatigue in the eye, the strain with which it is used may be interpreted solely by occipital or frontal head-

ache. 3. The long continuance of eye troubles may be the unsuspected source of insomnia, vertigo, nausea, and general failure of health. 4. In many cases the eye trouble becomes suddenly mischievous, owing to some failure of the general health, or to increased sensitiveness of the brain from moral or mental causes.

Taurocholate of Sodium, according to Sorrentino's experiments upon animals, is to be ranged among the cardiac remedies. Its action is marked by a slowing of the beats and lowering of the blood pressure. In large doses it always diminishes pressure, but produces a more or less noticeable acceleration of the beats. The slowing of the pulse is due to an excitation of the moderator ganglia. The acceleration which follows the use of toxic doses is due to paralysis of these ganglia. The diminution in pressure is in connection with excitation of the moderating apparatus of the heart and with the vascular dilatation. Toxic doses lower the pressure because they paralyze the myocardium. Vascular dilatation is a consequence of a peripheric action of the drug. Prolonged use of taurocholate of sodium alters the blood's composition in diminishing the number of red globules and the proportions of hæmoglobin.—*La Medicina Contemporanea*, January, 1896.

Membranous Sore Throat.—Lennox Brown states that twelve different varieties of membranous sore throat exist. They are as follows: (1) Contains nothing but the diphtheria bacillus. (2) The diphtheria bacillus associated with streptococci. (3) Diphtheria bacilli, streptococci, and staphylococci. (4) Diphtheria bacilli, streptococci, and diplococci. (5) Diphtheria bacilli and diplococci. (These are all varieties of true diphtheria.) (6) The sixth variety of membranous sore throat contains streptococci only. (7) Streptococci and diplococci. (8) Staphylococci only. (9) Staphylococci and diplococci. (10) Diplococci only. (11) Diplococci and a mycelium. (12) The twelfth is indeterminate. These last seven varieties are non-diphtheritic, or pseudo-diphtheritic in character.—DR. MERRITT, *Occidental Medical Times*, April, 1896.

Uterine Cancer.—Dr. Kessler believes that the diagnosis of cancer is not very difficult in the majority of cases. The text-books lead us to believe that it is always associated with cachexia; the suffering expression of the face, very frequent hemorrhages, fetid discharges, etc., are not always present. But a serous discharge, a bleeding between menstrual periods, and particularly a hemorrhage after the menopause, should make one very suspicious of malignant disease. He deprecates the practice of giving ergot or styptics in uterine hemorrhages when one suspects carcinoma, because while using these drugs the disease is progressing and valuable time is lost.—*St. Petersburg med. Woch.*, September 28, 1895.

Phthisis.—1. In early phthisis (catarrhal stage) to give comparative rest and relaxation to affected lung tissue. 2. In the stage of consolidation, to secure the same results, thereby limiting the risk of extension, and to promote elimination of the disease products by improving the circulation in and about the diseased area, and to facilitate expectoration. 3. In the stage of cavitation, to promote closing of cavities by directing healthy lung to encroach on the diseased area instead of relying on natural processes of cicatrization. 4. Diminished tendency to hemorrhage by reduced tension on vessels and cicatricial traction on vessel walls. 5. The ultimate object is to obtain a smaller thoracic cavity filled with healthy lung instead of an enlarged thoracic cavity partly filled with diseased lung.—DR. TIDEX, *British Medical Journal*.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOLIDAY AND LITERATURE—BLUE BOOKS—VACCINATION REPORT—INFANT - LIFE PROTECTION—POOR-LAW SUPERANNUATION ACT—IRISH WORKHOUSES—THE WATER FAMINE—DENTAL ASSOCIATION—VIVISECTION REPORT—SIR F. R. CRUISE—THE LATE P. Y. GOWLLAND.

LONDON, August 28, 1896.

WE are quite in the autumn holiday. All who can do so are either shooting or eating grouse. London is empty—says society. But there are still some four million of human beings in the metropolis, and an ample supply of doctors to attend them. When it is said all the doctors are out of town, no more is intended than when society so declares of every one. Amusement is looked for by those who remain, but there is plenty of work and the literature issued is not without a considerable proportion of the heavy kind. Reports and blue books are seldom light reading, but they have to be grappled with, even in holiday time.

I have furnished you already with a brief notice of the vaccination report, which "it is to be hoped," as the commissioners say, "will stimulate belief in the efficacy of vaccination." The report was completed on the 13th, since which time a number of statements have appeared as to its tenor, some difficult to reconcile with others, but you may accept what I have previously written as accurate. The distribution of the report to the public will probably be delayed for another week or ten days, but of course some of us have secured early copies. Some papers have been so early with their reports that complaint is made of improper or indiscreet revelations.

If all men were reasonable, this report, although expressed in terms so cold that some already stigmatize it as half-hearted, would put an end to agitation. But the antivacs take their defeat badly, and we have not yet done with them. The minority statement of those dissenting from some of the views of the majority is already held up, as showing that a royal commission cannot be convinced to the extent of unanimity. But this was, of course, expected when some of the most prejudiced antivacs were nominated on the commission. The minority claim that compulsion is neither expedient nor just, as there exists a sufficient amount of conscientious objection to making martyrs of recalcitrants, and they say it is unjust to override parental responsibility and disregard parental feeling. Yet those who sign this must be aware that the law does override such feelings for the good of the community. It is even necessary to restrain parents from cruelty, negligence, and other things, while they are compelled to educate their children and do other things, too, which are for the child's good. Law may be said to generally involve compulsion or restraint. As to the "conscientious objection," it must seem really funny to most people to couple conscience with vaccination. If it had not been a profitable game to set up agitation, no one would have heard of conscience in the matter, and when brought forward by agitators it is merely regarded as providing cranks with an excuse. But the rights of conscience are serious, and the commissioners have treated the objection seriously, though it is to be feared their logic will not convert recalcitrants.

The extreme moderation of the report should be more convincing than a stronger statement, and eventually will have full weight, though at present this influence is scarcely felt. But I will pass on to other

subjects, for this one is likely to demand attention later on.

The House of Lords committee on the infant-life protection bill has finished its report. The bill was among the "slaughtered innocents" of the session, but from this report we may augur well for its future. The committee sat seven days and examined nineteen witnesses. Some evidence went to show that a single infant is rarely taken with a view of profit, and is usually well looked after. The committee, therefore, do not propose to extend the act to the keeping of one, but the farming of two will bring the persons under its provisions, which in the main are satisfactory and will to a great extent protect the children who are put out.

The Lords, after all, rushed through the poor-law officers superannuation act, though it was so late that most of the newspapers reported its loss. However, "all's well that ends well," and the officers are expressing satisfaction. The act applies to a great army of poor-law officials, including the medical. A deduction of from two to three per cent. of the salaries is compulsory, and will secure a pension after sixty years of age. It is allowed for those in the service to exclude themselves from its operation by notice within the next three months. Those who do not contemplate remaining in the service will, of course, do this. I should think a great number of poor-law doctors do not take up the service with a view of spending their lives in it, and if they do not stay till they are sixty they will lose their premiums. To the great disappointment of the Irish service, the act does not extend to Ireland.

This reminds me of the question of reform in Irish workhouses, which has been demanded for some time past. A number of persons in London have been active in this movement, and now a circular letter, signed by Lord Monteagle, has been issued, inviting us to meet in Dublin on October 1st or 2d. As the date coincides with the opening of the winter session here, a number of medical men will be unable to accept.

The "water famine," as the scarcity at the East End of London has been dubbed by the newspapers, continues to cause great inconvenience and distress. Many diseases are attributed to this cause by the public, and the conduct of the water company will greatly strengthen the cry for the abolition of the water monopolies and the control of the supply by a single representative body.

The dentists succeeded the dermatologists with a week's meeting in London, where the British Dental Association held its annual meeting. Mr. Canton, the president, dealt in his address with dental education and politics. The great progress made since the dental act has shown how large is the majority of those who have shown themselves worthy professional colleagues, and how desirous they are to put down quackery in their department. A number of careful papers were submitted and discussed. There was a reception at the College of Surgeons, the buildings having been granted by the council for this purpose. Of course there were a dinner, a garden party, and an excursion, to none of which did I go. The most interesting part of the scientific proceedings was, perhaps, the demonstrations. Microscopic preparations, micro-photographs, skiagraphs, and diagrams abounded. The association numbers nine hundred and thirty members, but there are several other societies devoted to the cultivation of the dental art, the oldest being the Odontological, which dates from before the act of 1878, the mark of a new dental era in England. Next year the association is to meet in Dublin.

The report of the inspector under the vivisection

acts for 1895 has been issued. There were three hundred and seventy-five experiments performed under license, excluding hypodermic injections and inoculations, which numbered twenty-seven hundred and forty-four. These last have really no claim to the title of vivisection, and it seems absurd to subject to supervision practically painless proceedings which are daily undertaken on our patients without the faddists objecting.

Dr. F. R. Cruise, of Dublin, has received a knighthood, to the satisfaction of his brethren.

Yesterday—no, the day before—the Chemists' Exhibition offered a great number of articles of interest to medical men for inspection by all and sundry.

The death, on August 11th, of Mr. P. Y. Gowlland, F.R.C.S., removes a personality much respected among leaders of the profession. He left Finsbury Square, where he had practised some forty years, on his retirement two or three years ago. He was assistant surgeon and teacher of anatomy at the London Hospital for a few years in his early career, but became surgeon to St. Mark's Hospital for Fistula, from which circumstance he devoted his powers to the specialty of which he was for so long the chief ornament. As a teacher he was popular with students, and regret was felt when at quite an early age he resigned from the London Hospital. This step, however, was necessitated by his great success in practice and his devotion to his specialty, which prevented him giving to the work of teaching the time and energy which he felt were due. Mr. Gowlland was an artist and would rapidly sketch whatever he was demonstrating. He drew and painted his most interesting cases, and so accumulated an immense number of pathological illustrations of diseased conditions of the rectum and adjoining parts. I knew him well enough, and in looking over his collections discussed with him which would be best for publishing. Once I selected to illustrate some important points a certain set which he had shown me and which he acknowledged should be published. I arranged, too, for these to be lithographed for him while he committed to paper his comments upon them. But he was always too busy to do so, and the matter remained in abeyance. He was almost fastidious in this kind of work, and his efforts to combine accuracy with artistic finish often resulted in his dissatisfaction with work for which others had only admiration. He was a keen sportsman, and when he could take a holiday it was with gun or line that he passed his time. Circumstances separated us for some time, and he retired and took a house at the West End. And now at seventy-two years of age he has joined the majority, leaving a widow and a married daughter. His son died several years ago, to the lasting regret of his parents and sister.

THE MORPHOLOGY OF THE BLOOD IN TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In connection with the presentation of Dr. Holmes' and my papers in last week's issue of the MEDICAL RECORD, will you please announce the action of the Colorado State Medical Society in renewing the award and continuing the committee, of which I have the honor to be chairman, to give a prize of one hundred dollars for the best essay on the detection of tuberculosis by the microscopical examination of the blood. Of course, the award is altogether too small, considering the labor and skill required to accomplish this task, and should another society, or any individual wish to increase the amount, the committee will be only too glad to watch over the contribution and see that it be not unworthily bestowed. The task requires not only that the disease

shall be diagnosed by the blood examination alone (practically without the patient being seen), but that the various manifestations of tuberculosis shall be differentiated, and that the system of calculation as well as the technique of procedure shall be plainly elaborated, so that any skilled microscopist may arrive at a similar conclusion.

It is a gratification to have brought so nearly in sight the certainty of accomplishing what I have long thought a possibility. We shall be pleased to have others compete for the honor Dr. Holmes is striving for, and will gladly enter into correspondence with any such. Meantime, I will refer to Dr. Holmes' excellent paper for the reason for this enthusiasm. It is not only the diagnosis of tuberculosis in its various phases which is at hand, but a means to measure accurately the different methods of treatment, not excluding the equal of any yet advanced, that of the preferable climate.

CHARLES DENISON, M.D.

DENVER, COL.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 5, 1896:

	Cases.	Deaths.
Tuberculosis.....	199	88
Typhoid fever.....	28	8
Scarlet fever.....	22	4
Cerebro-spinal meningitis.....	1	1
Measles.....	26	4
Diphtheria.....	142	27
Small-pox.....	0	0

A Portable Crematory for incinerating the bodies of those who die in battle has been invented by a Polish engineer.

Progress.—"Medical science has made such progress," said the doctor, when speaking of his profession, "that it is almost impossible for anybody to be buried alive now." Then he wondered why everybody laughed.—*Boston Courier*.

Nature's Sarcasm.—People laughed a few years ago when the worst-diseased herd of cattle in a New England State were found on the farm of its agricultural college. The valuable animals were killed and the State stood the loss. So now people laugh when they read the reports of the ravages of the army worm here and there and notice that the greatest destruction it has caused in this State is on the farm of our State Agricultural College at Kingston.—*Providence Telegram*.

Sufficiency of Milk after Birth.—Dr. Buchmann (*British Medical Journal*) wished to ascertain the proportion of cases in which the mother was able to suckle her child. Out of the one hundred and twenty-six cases, eighty-three (or 65.9 per cent.) had sufficient milk when discharged between the tenth and twelfth day. The percentages recently reported from Basle and Stuttgart were much lower. More statistics of this kind are called for, as they throw much light on the health and strength of women in different regions.

Results and Methods of Surgical Operations.—Dr. Stimson (*Annals of Surgery*, vol. xxiii., No. 6) draws the following conclusions: (1) It may be confidently expected that, with the aid of assistants trained for and constantly exercised in the prepara-

tions for and the conduct of operations, and with special attention to the cleanliness of the hands, a clean surgical wound will escape infection and will heal without suppuration: but that without such skilled aid, and without the security given by the constant practice of the assistants in hospital, the same measure of success is not to be expected. (2) It is probable that a certain measure of infection by germs in the air, or in the patient himself, takes place in an unknown proportion of cases, but that it is habitually so slight that the resistant powers of the tissues are able to prevent its manifestation and spread. We are perhaps justified in offering the low vitality of the patient as an explanation of the occasional sporadic cases of suppuration that occur in long series of otherwise successful operations. (3) We have in large intravenous injections of salt solution, during or after an operation or a severe injury, a valuable means of averting an impending death by shock or hemorrhage. (4) Habitual immunity from infection creates an operative confidence that may lead to a neglect to give full weight to such warnings or contraindications as might be found in the probable severity of the operation or in the reduction of the patient's vitality, especially in malignant disease.

Puerperal Fever.—Dr. Montgomery (*Journal American Medical Association*, August 1, 1896) advises early curettement. If the condition is due to putrid intoxication this procedure, followed by irrigation and drainage, will give prompt relief. In streptococcus infection the germs are embedded in the mucous membrane, sinuses, and wall of the uterus, so that curettement would not accomplish their complete removal and would afford more surface for ptomain absorption. Hysterectomy has been advocated, but it is a question whether in this form of infection the tissues have not been invaded to such a degree that the removal of the uterus would be ineffectual. The first aim should be the establishment of immunity; then local manifestations should be treated as they make their appearance, with the assurance that farther spread will be avoided.

Gastric Ulcer.—Dr. Deale (*Maryland Medical Journal*) writes: "It was a surprising revelation to me that numerous autopsies have shown gastric ulcer to be present, either in the fresh state or as healed cicatrices, in from two to five per cent. of deaths from all causes, and it is only fair to add that the proportion approximates nearer the latter (five per cent.) than the former."

Death after Flooding.—Dr. Tarnier (*Asclepiad*), after pointing out that forceps are seldom or never used in accouchement except in uterine inertia, a source of hemorrhage, and giving an instance or two of the necropsy of women who have died after flooding which was not profuse enough to deplete the circulatory system, advises physicians to be slow in finding fault with a colleague for losing a patient after flooding, as it frequently happens that a healthy-appearing woman may have some radical organic affection coexistent with pregnancy, which may carry her off without the flooding being to blame.

Care of Premature Infants.—Dr. Gilbert, before the Kentucky State Medical Society, June, 1896, said that statistics show that twenty per cent. of infants born at sixth month have survived, thirty-five per cent. at seventh month, and at eighth month eighty-five per cent. It is too often the custom to turn premature infants over to old women, without any attention. A physician is inexcusable if he allows a premature infant to die from sheer neglect. To preserve life especial attention must be paid to the maintenance of bodily temperature, proper feeding, prevention of injury by handling. The temperature should be main-

tained at 100° F.; evaporation of moisture goes on from the body no matter how closely it is wrapped in cotton or clothing. Incubation is the best method of maintaining bodily temperature. The apparatus recommended consists of two tin boxes, with a two-inch space between for warm water. The water is heated by a coal-oil lamp placed under a small copper water box connecting with a water chamber by small pipes. The top of the box is open to allow the infant air and light. Any tight box may be improvised. Feeding is important, mothers' milk being the best food: lavage may be used. A mixture which has proved successful in the author's hands is as follows:

R Sweet milk, fresh	ij.	60.
Cream, fresh	iiij.	90.
Warm water, sterilized	x.	300.
Sugar of milk	℥i.	4.
Common salt	℥i.	1.30

This should be diluted for a premature infant. The infant after birth should be anointed with warm lard, the vernix having been wiped off; no water should be used at the first cleansing, nor should the infant be washed until it is three weeks of age.

Ectopic Pregnancy.—Dr. MacMonagle (*Southern California Practitioner*, May 26th), from a review of the literature on this subject and from his own experience, draws the following conclusions: 1. A large majority of ectopic gestations begin in some part of the tube. 2. Pain is an important and almost constant symptom. 3. A growing ovum must burst the tube. 4. Rupture must take place into either the peritoneal cavity or the broad ligament. 5. When discovered, ectopic pregnancy should be operated on as soon as arrangements can be made for a careful and perfectly aseptic operation. 6. An exploratory incision is justified when there is a reasonable assurance of ectopic pregnancy. 7. Rupture into the peritoneal cavity, with hemorrhage, demands operation at once. 8. The suprapubic operation is the best in a large majority of cases. 9. The vaginal operation should be chosen in the cases in which one feels sure the mass is well walled off from above and can be easily reached from the vagina. 10. In doing the vaginal operation one should be prepared to complete it from above in case of complications. 11. Early operation and removal of the tube, sac, and contents will give the best results.

Cocaine in Surgery.—1. The use of cocaine should not be abandoned because its irrational employment has produced deleterious results. 2. Always make a thorough physical examination of the patient before injecting the drug. 3. It should not be used in cases showing organic diseases of the brain, heart, lungs, or kidneys, or in persons of neurotic diathesis. 4. Children bear it fully as well as adults. 5. The patient should always be placed in a recumbent position prior to its employment. 6. Constriction should be used whenever possible to limit the action of the drug to a desired area. 7. Use a freshly prepared solution for each case. 8. Distilled water should always be employed, to which phenic, salicylic, or boric acid should be added. 9. A two-per-cent. solution has a better effect, and is safer than solutions of greater strength. 10. Never inject a larger quantity than one and one-eighth grains when no constriction is used. 11. About the head, face, and neck, one-third of a grain should never be exceeded. 12. When constriction is possible, the dose may be as large as two grains. 13. Every slight physiological effect is not necessarily to be taken as cause for alarm. 14. Cocaine does have effect upon inflamed tissues. 15. In case alarming symptoms occur, use amyl nitrite, strychnine, digitalis, ether, or ammonia.—*Codex Medicus*.

THE TREATMENT OF PNEUMONIA.

By W. N. MACARTNEY, M.D.,

FORT COVINGTON, N. Y.

THE editor of the *MEDICAL RECORD*, in the issue of December 1, 1894, says that "many drugs have a reputed value in pneumonia, but none are yet accepted as in any sense standard remedies in the disease," and there can be no doubt of the truthfulness of this statement. During the past fifty years the treatment of pneumonia has passed through many phases, radical in their nature, from free venesection down through tartar emetic, veratrum viride, and a host of other "cures" to the more modern digitalis treatment, the supporting and expectant plan, or the germ-from-Germany sero-therapy.

Much has been written on this subject, and rightfully, since no disease merits more careful attention. Pneumonia is an extremely common disease; it is found in all countries and in all parts of our own country. Every practitioner is familiar with it—perhaps too familiar with it, for its prevalence and fatality are often taken as a matter of course, although the death rate from this malady is simply enormous.

The ravages made by this disease were forcibly brought home to me in looking up the statistics in my own locality, when I found to my surprise that pneumonia headed the list of fatal diseases during the previous decade, with consumption second, while diphtheria, then epidemic and causing from its severity much alarm, took a low third place. That our experience was not an isolated one was also apparent, for statistics from various localities, which it is unnecessary to dwell upon at length, showed this. Delafield, for instance, gives the proportion of deaths from pneumonia in the States above the thirty-ninth parallel as 61.43 per thousand deaths, while below that parallel it is 93.70. If this were not enough, Miller states that during the past ten years 15,544 deaths occurred from respiratory diseases in the Moscow Orphan Asylum, in a total of 155,459 deaths from all causes, and that of these 14,411, or 92 per cent., were from pneumonia. In the city of New York, to quote a more recent example, the mortality during the four weeks beginning March 1 and ending March 28, 1896, the reports being issued weekly, not by months, was 658, while the mortality from consumption, the next highest on the list, was but 409. The total fatality from small-pox, measles, scarlatina, diphtheria and croup, whooping-cough, typhoid fever, malarial and cerebro-spinal fever during this length of time was 363. It will be seen at a glance that the death rate in the great metropolis during these four weeks exceeded the sum total of the mortality from all zymotic diseases by more than eighty-one per cent., and that this is not an exceptional instance can be easily verified by a study of the records from month to month. March reports from Philadelphia show much the same death rates.

Walshe gives this affection the third place in the catalogue of fatal diseases. On what grounds this es-

timate is based I cannot say, but undoubtedly of late years it would stand much higher, owing to its greater prevalence in connection with the grippe. Certainly all records which I can find would go to show that at present pneumonia has the greatest fatality of all diseases in this broad land of ours. Have we become so accustomed to this appalling mortality that it excites no comment? It would seem so, for should one-tenth the number of people who die annually of pneumonia in the United States lose their lives from Asiatic cholera or in a Johnstown flood, the country would be wild with horror. True, the latter would be to some extent preventable deaths, but can nothing be done to diminish the enormous mortality from this one pulmonary disorder?

During the years 1890-1896 pneumonia prevailed to an unusual extent in northern New York, owing in a large measure to its association with epidemic influenza. Previous to 1892 I treated pneumonia after established methods, or at least after modern and popular methods. The keynote of the treatment was to support the patient until the crisis was passed. Poultices were applied, with cotton-batting jackets, absolute rest, nutritious fluid food, stimulants, etc. Various drugs were used, as seemed indicated—quinine, Dover's powder, aconite, digitalis, etc. Phenacetin, acetanilid, and other coal-tar derivatives were tried, but soon abandoned as decidedly injurious and unsafe. The fever went down under their use. The patient frequently followed.

Under this general supporting plan of treatment, based on the view that pneumonia was a self-limited disease, and the chief object of treatment was to keep the patient alive long enough to allow the disease to run its course and spend its energy—a plan of treatment which I was taught at college, a plan which I had afterward seen followed in the hospitals, a plan of treatment which most of our modern text-books commend, and which is generally endorsed by the profession at the present day—under this general method, based on the doctrine of self-limitation, my mortality was about sixteen per cent., as nearly as it could be estimated, for up to this time I had kept no very accurate record of my pneumonia cases.

On looking up statistics, I found the mortality estimated variously. "Hospital statistics show twenty to forty per cent." The Montreal General Hospital gave a mortality of 20.4 per cent. Of 3,969 cases at Charity Hospital, New Orleans, 28.01 per cent. died. The Massachusetts General Hospital records, according to Drs. Townsend and Coolidge, showed a mortality of 28 per cent. of late years. These statistics should have comforted me, and they did to some degree afford consolation; but the mortality in the Massachusetts General Hospital from 1822 to 1832 was shown to be but 10 per cent., while the reasons advanced for the increased fatality in the later years seemed to me unsatisfactory. According to the report, when the intemperate, the aged, and the complicated cases were excluded, the mortality was reduced from 28 per cent. to 10 per cent., which, if an inherent feature of the disease, was still a high mortality.

The closer my scrutiny of all available records the more dissatisfied did I become, and my own death rate,

though averaging well, seemed unnecessarily large. For these reasons and others, my confidence in the etiology and treatment of this disease was so shaken that for a time I followed no definite mode of treatment, but tried various methods or treated the cases symptomatically, while eventually the result of this state of uncertainty and skepticism was a radical and sweeping change in my general manner of treating this affection.

The central idea of the modern management of pneumonia is, if I judge correctly, that this being a self-limited disease, due to germ infection, the treatment in accordance with this theory should be to place the patient under the most favorable conditions, keeping up his strength until the disease runs its course. In other words, the treatment is purely expectant or symptomatic, as the case may require. This view is in marked contrast to that held years ago, when pneumonia was considered an inflammation of the lung tissue, venesection and depletion being in vogue. Which is right? Statistics certainly do not prove very much for our later-day methods, and between the two extremes there may be some truth.

What is the specific cause of pneumonia? It is perhaps safest to say, *sub judice lis est*. The pneumococcus of Fraenkel is given as the immediate and direct originator of croupous pneumonia; but the pneumococcus also occurs in catarrhal pneumonia, in middle-ear disease, in endocarditis, in cerebro-spinal fever, in pleuritis unconnected with pneumonia. It seems to be normally found in the human mouth. The bacillus of Friedländer, bacillus of influenza, streptococcus pyogenes, and staphylococcus also "cause" pneumonia. Certain cases also have been reported as due to the proteus vulgaris and the bacterium coli commune. The microscope and the culture tube have so far given us nothing we can rely on, and the evidence we have is altogether too vague, too indefinite, to be accepted as absolute proof of the microbic origin of this malady.

Clinically, also, there are many things which require explanation if pneumonia is to be regarded as essentially of microbic origin. Why does it occur so commonly in the later stages of exhausting diseases, in old age, in connection with cardiac disorders? In 1888 I treated a case of dilatation of the heart through four attacks of pneumonia within a period of three months. Why should one attack predispose to others? Why should it occur so often after fracture of the neck of the femur? What is its mode of infection, its period of incubation?

Why can it be aborted or jugulated if it is a germ disease? But some say pneumonia cannot be aborted. Osler, for instance, says, in his "Practice," p. 529: "Pneumonia is a self-limited disease and runs its course uninfluenced in any way by medicine. It can neither be aborted nor cut short by any known means at our command." This is a very strong declaration for even a man of his reputation to make. It is a statement, moreover, which is opposed to the assertions of men such as Austin Flint the elder, and others, who say that pneumonia can be aborted and that they do abort pneumonias. "We must never assume that which is incapable of proof," says Lewes, in "The Physiology of Common Life," and the position which Osler takes is untenable. "There is a difference between assertion and demonstration," as Macauley remarks, and the assertion that pneumonia cannot be cut short is, on the face of it, too sweeping and practically insusceptible of proof, for in order to establish this it would be necessary to show that no case of pneumonia ever has been or could be aborted, a thing manifestly impossible to demonstrate, requiring as it would an accurate knowledge of every case since Adam and Eve left paradise. *Per contra*, proof that a single

case has been jugulated by medicine or other means is amply sufficient to disprove Osler's assertion.

Many authors there are who uphold the theory of jugulation. All are not so conservative as Flint, who says: "The disease is self-aborting or may be aborted in some cases." I venture to say that there are few physicians who have not seen pneumonia cut short in its early stage. Within the last three years I have treated one hundred and twenty cases of pneumonia, and of this number sixty-seven, or 55.8 per cent., were cut short, not running their full course. Many of these were already well marked at my first visit, with all the physical signs and symptoms, and to say that in 55.8 per cent. of the cases there was a mistake in diagnosis could hardly be called argument.

Some practitioners may never have seen pneumonia cut short, and dead-house statistics will probably substantiate them. There are individuals who have never seen partridges "drumming." They don't drum much in confinement, nor would one readily discover how they do it by examining them ever so carefully as they hang by their legs, heads down, in the market. So, too, it is not easy to demonstrate by post-mortem examinations that pneumonia is ever jugulated, for these patients, unfortunately for dead-house statisticians, get well when the pneumonia aborts. Yet this does not prove that partridges never drum or that pneumonia never aborts, some of our modern authors to the contrary notwithstanding. Too large a number of able diagnosticians, careful observers, logical reasoners, have seen pneumonia cut short, to allow us to give such assertions as that of Osler's credence.

If, on the other hand, pneumonia can be jugulated, how reconcile this with the orthodox doctrine of the pneumococcus of Fraenkel *et al.*? Can we sweat out small-pox or typhoid in a few hours, or have we a new-style, unique, law-unto-itself sort of a germ to deal with—a germ forever sitting in our outside gates, a germ which threatens the very citadels of life when once admitted, which defies antiseptics, eludes inoculation, laughs at "trinity pills," but subsides quietly and at once when the circulation is equalized? Surely a strange germ and an outlaw from its kind.

Is pneumonia infectious, contagious, or both? Probably it is in the pathological laboratory; it has hardly been satisfactorily proven by clinical records. Certain instances are given in which several in the same family or closely associated have developed the disease about the same time. I have a case in point. Three persons—a man, his wife, and an adopted daughter—living in a farmhouse some distance from the road, were taken with influenza. There were but two beds in the house, one of which was usually occupied by the old couple, the girl sleeping in the other. A neighbor calling in found all three sick, and I was summoned. The woman was then suffering from pneumonia of two days' standing, while the man had pneumonia also of more recent origin, and on the following day the girl developed the same malady. The woman died, the other two recovering. It seemed a clear case of pneumonic infection, possibly of contagion; yet on closer scrutiny it appeared that in the beginning the wife as nurse had put the husband and daughter in the two beds, and she herself, the subject of the grippe, had slept on a lounge. She then developed pneumonia, took the bed occupied by her husband, he assuming charge. Then the husband came down with pneumonia while reclining on the lounge, and the girl arose, gave him her room, took the lounge—and pneumonia. It was ascertained that all three of them had developed the pneumonic process while lying, with lungs irritated and congested by the grippe and their systems depressed by it, on the couch next an outside wall, in rough February weather, with the thermometer many degrees below zero, and with a wide crack in the wall just below

the level of the lounge, through which the cold wind was freely blowing. Were these people the victims of infection by the diplococcus pneumoniae? They may have been. Equally true, Mars may be inhabited. But the crack in the wall was there; it did not require a high-power objective for demonstration.

Then there are instances of epidemics of pneumonia in barracks and prisons. These require more thorough investigation before they can be accepted as proof positive of its infectiousness, especially in view of the possibility that some other infective agent may have been at work. In some epidemics of scarlatina nearly every case develops nephritis, yet we are hardly warranted in considering nephritis either infectious or contagious.

Pneumonia may be an infective disease with a period of incubation extremely short and a specific organism as a causative agent. I am too thorough a believer in the germ theory in general to deny this, but a safe assertion would be that at the present day we do not know its cause. This certainly is safer than assuming a knowledge which we do not possess. More light is needed before we accept theory as fact. Theory is all well enough as theory, but it is well to remember that it is not proof, and while the theory of the bacterial origin of this disease has been furnished, the proof is still incomplete, the obstacles in the way of the unqualified acceptance of it being many and troublesome.

What is the cause of the great mortality in pneumonia? Is it an inherent and essential feature of the disease? Is it that the disease is necessarily fatal in about one out of four average cases? Are our methods of treatment faulty? Because of the enormous mortality solely from this one disease, this is a subject well worthy of careful and lucid consideration. To one who keeps an eye on the obituary column in our medical journals, it would seem to be a disease peculiarly fatal to physicians, and that, verily, when we have pneumonia,

"To our graves we walk
In the thick footprints of departed men."

Austin Flint says: "The treatment is in the main supporting; . . . support the powers of life." According to Loomis: "The success of modern methods of treatment based on this belief bears evidence to its being a general self-limiting acute febrile disease." The success of modern methods has been shown as a mortality of one out of every four cases. Loomis himself fell a victim to the disease, and the "evidence" which the "treatment based on this belief" bears is like the handwriting on the wall.

"And we shall feed like oxen at a stall,
The better cherish'd still the nearer death."

Why should the treatment be supporting? Practically all authors are agreed that the usual cause of death is cardiac failure. Is this heart failure due to exhaustion? It is a matter of common observation even among the laity that robust people are often seemingly overwhelmed with the disease; that it attacks the vigorous as well as the delicate. Does a strong, robust, well-nourished man die of exhaustion on the fifth or sixth day of a typhoid fever? Does he not, on the contrary, usually live through four weeks of high fever on a liquid diet (or something lighter still if the fasting treatment of Dr. Page be followed), and eventually recover? I have seen patients dying of pneumonia when their muscular strength was at the time greater than that of their medical attendant, as evidenced by the force required to restrain them in their delirium; in whom the pulse was full and strong up to the time of the superaddition of congestion and œdema. In com-

parison with that other acute febrile disease, typhoid, does it seem that they died of exhaustion on the fourth or fifth day? Is this common sense?

On the other hand, if the high temperature disorganizes the heart muscle, why does it act so rapidly in pneumonia and so slowly in typhoid and other febrile disorders? When a pneumonia patient is *in extremis*, due to a temperature of 103° F. for four or five days, if phenacetin or acetanilid is given and his temperature is thus reduced, will that lessen his tendency to cardiac failure or increase it? Pepper says the cardiac exhaustion is due to the poison of bacteria. But what leucomain is produced by the pneumococcus which is so prompt and powerful a cardiac poison as to produce these rapid effects? Has this morbid agent, this powerful toxin, toxalbumin, or pneumotoxin been demonstrated? Theory is not proof. Speculation and conjecture are not evidence.

The patient certainly does not die of pulmonary or respiratory failure. Pleurisy gives us no such mortality, nor does it cause death by respiratory exhaustion, even though one lung is compressed by fluid effusion into a small space the size of a hand. Empyema does not kill in five days, though the fever may be high and an entire lung rendered useless, with septic intoxication added. In New York City, during the week ending March 28, 1896 (the latest available report), to contrast the deaths from pneumonia with those from pleurisy, there were one hundred and eighty-two deaths from the former, one from pleurisy, none from empyema. Phthisical patients do not die of respiratory failure, though the lungs may be extensively disorganized. Careful observations at the bedside show that respiratory failure is not the cause of death in pneumonia in the vast majority of cases.

What kind of heart failure is it that kills off the robust and the weak in such appalling numbers? Much has been written of the morbid anatomy of pneumonia, of the consolidation of lung, the fibrinous exudate into the air vesicles being minutely described and dwelt upon, while the vascular changes are dismissed with a few words descriptive of the hyperæmic condition. Prior to hepatization many of the air vesicles are collapsed from the pressure of the swollen and tortuous vessels. The exudation occurs with the stage of hepatization. Is the exudate the cause of the hyperæmia or the effect? Virchow has proved that pneumonic processes can be established when large branches of the pulmonary artery are plugged. It is thoroughly understood also that passive pulmonary hyperæmia of long standing, due either to cardiac affections or to hypostasis, leads to the establishment of pneumonic processes. Sudden chilling of the surface, driving the blood to the internal organs, is the commonest exciting cause under which slowing of the pulmonary circulation from congestion results; the lungs, being spongy, elastic organs, furnish a point of small resistance. Stasis should be followed by exudation into the alveoli. Exudates occur in thrombosis and in circulatory disturbances in general; the exudates are dependent upon the circulatory changes, and absorption is rapidly resultant when the circulation is re-established on normal lines. How else but in some similar way can we explain the quick clearing up of a lung consolidated by pneumonia? The inflammatory theory will not explain it, for this is not the course of an inflammation. It is an open question, therefore, if too much attention has not been paid to the exudate into the air sacs and not enough to the vascular changes. Certain it is that we have a coagulative process resembling in some respects venous thrombosis in the suddenness of its occurrence, in the vascular changes resulting, in the fact that we have venous blood in the pulmonary artery as a circulatory medium. We do not understand the pathology of phlebitis. Neither

do we understand that of pneumonia. Let us be as candid in the one case as in the other.

It seems to me that Ribbert, of Bonn, makes a centre shot when he states that "pneumonic processes are attended with coagula within the blood-vessels in the form of fibrous thrombi, and within the capillaries." Osler says: "If the lung has been removed before the heart, it is not uncommon to find solid moulds of clot filling the blood-vessels. . . . The heart is distended with firm, tenacious coagula, which can be withdrawn from the vessels as dendritic moulds. In no other acute disease do we meet with coagula of such solidity and firmness." Other authors have it that the pulmonary vessels may contain thrombi with fibrin formations in the capillaries of the portion of lung affected with the pneumonic process. The enormous increase in the fibrin factors has long been known. Given this condition referred to, and the exudate must follow. Which is the primary process and therefore the more important?

Delafield says: "The pressure of exudate on the blood-vessels may cause necrosis of the pulmonary tissue with resulting gangrene." It seems difficult to prove that the necrosis is brought about in this way. Plugging of the pulmonary vessels may occur and the exudate may follow; and the pressure of this exudate on the bronchial vessels which furnish the remaining blood supply might be sufficient to cause gangrene. Looking at it in this way, it would be a logical sequence.

Pneumonia is largely fatal in proportion to the extent of lung structure involved. Some authors deny this. Perhaps they prefer double pneumonias to one-sided—most of us do not. Why this fatality when much lung is involved? The answer is, obstruction to the pulmonary circulation. If the primary trouble in pneumonia were circulatory, it would explain many things otherwise difficult of comprehension. It would make manifest Loomis' statements that "most sudden deaths in the old are from acute lobar pneumonia," and that "nine-tenths of all deaths after the sixty-fifth year are caused by lobar pneumonia." One author asserts that "pneumonia is the natural death of the old man." It would account for the suddenness of onset of pneumonia, its occurrence after exposure, in connection with cardiac diseases, in long-continued fevers, in cases of fracture, of debility; it would render intelligible the almost miraculous way in which resolution of the consolidation takes place in so short a time; it would make plain the cyanosis and the heart failure; it would make clear much which under accepted views is difficult of elucidation.

It is far from the purpose of the writer of this paper to formulate a new theory of the essential and specific cause of pneumonia. The etiology of this affection is still involved in obscurity and the various theories offered are far in advance of the facts so far established. We need more painstaking investigations and less airing of individual opinions, but there is good reason to believe that the morbid process, whatever its origin, is more a circulatory than a strictly febrile or inflammatory disturbance and the view that the primary seat of the pathological process will be found eventually in the vascular mechanism of the lung, rather than in the air vesicles, commends itself to a sober judgment. In the absence of further knowledge of the various pathogenic bacteria of pneumonia and the precise rôle they play, they may be for the present disregarded as not essential to the purpose of this paper. From the point of view that the disease process is circulatory the fibrinous exudate in the air-cells is of small importance. See how quickly it will disappear by absorption when the circulation is re-established. Take the ligature from around your finger and watch the swelling subside. Cardiac failure, not

respiratory failure, is to be feared, and we need to study the circulatory changes, not the fibrinous exudate.

Given stasis from fibrous thrombi in the vessels of a portion of the lung, and what would occur in natural sequence? Increased labor thrown on the heart. Not on the heart as a whole, but on the right heart, the light horse in the team. Ordinarily its work is not difficult, its circuit being short and easy. It pumps blood through the pulmonary artery, through spongy lungs, back into the left heart. There is little necessity for thick muscular walls: therefore its walls are thin. The left heart on the contrary is strong and muscular, for it has a long difficult circuit, up-hill, down-hill, and back again. It must be thick and strong. But the right heart has comparatively little lifting to do ordinarily. Then, if with pneumonia we have fibrin formations or other obstructions in the capillaries and pulmonary vessels of an extensive area of lung tissue, congestion perhaps of the remaining portion, possibly thrombi in the pulmonary vessels, or perchance pressure on the vessels from the exudate, insufficient, however, to cause necrosis, but enough with the rest seriously to embarrass the lesser circulation and heavily to tax the right heart, then what naturally follows in severe cases? Circulatory disturbances from pulmonary obstruction, collateral hyperæmia and œdema, fulness of the pulmonary artery from the obstruction, and—the beginning of the end—dilatation of the right heart, which labors and struggles. The natural outcome of this is fulness and damming-up in the vena cava superior and inferior, the right heart being unable to force the blood through the obstructed lungs as freely as usual, while the left heart, unhampered, is filling the veins and sending more blood to the right. Then comes the increased enlargement of the liver and spleen: the brain is congested, engorged, and delirium occurs. The right heart dilates further until possibly the valves no longer are competent; the heart, distended and choked with its own blood, is failing rapidly. We may now have a dicrotic pulse from insufficient filling of the vessels on the farther side of the barrier. General venous congestion with increased hyperæmia of the lungs, cyanosis from the venous accumulation, is next in order, while, the blue blood acting on the respiratory centres in the medulla, the breathing is more rapid, labored, and irregular. The fibrin factors being increased four hundred per cent., the struggling heart whips up the slowed blood current until, as a natural result, heart clot may follow.

Death is due to heart failure—not to heart failure as a whole, but essentially and specifically to failure of the right heart, and this right-heart failure is not due to fever, exhaustion, lack of oxygen, nor to septic poisoning, but is the legitimate result of a blockade in the pulmonary circulation. In other words, the right-heart failure is due directly to interference with the work of the right heart. When it is remembered that the right and left hearts are to a large degree separate pieces of mechanism, that the obstruction in pneumonia is in the lesser circulation, and that the right heart is the weaker, it seems almost trite to say that the cardiac failure is a right-heart failure; but when this doctrine is more fully established, its importance more generally recognized, and when the treatment is remodelled on this central idea, the mortality from pneumonia will be much reduced and phenacetin and acetanilid will be discarded in pneumonic cases.

As I have previously stated, the mortality in the first series of cases was about sixteen per cent. In the second series of one hundred and twenty consecutive cases, treated after the general method which is about to be described, the mortality was two, or 1.66 per cent. This list includes all cases, treated since

the time referred to, in my general practice. Cases seen in consultation, but under other plans of treatment by their attending physicians, cannot properly be included among my own cases and are therefore omitted. The cases constituting this series occurred in the same locality, under practically identical conditions, with the same nursing and hygienic surroundings, and so far as I can judge were of the same general severity as those previously mentioned. The sole difference was in the treatment. Certainly many of them were severe enough, so severe that I frequently gave an unfavorable prognosis, in the light of previous experience, and yet they recovered. Many of the patients were aged, a number being in their eighties. Some were feeble: some were alcoholic. A large number had double pneumonia. There were two cases of contusion pneumonia complicating fracture of the ribs. Some had typhoid pneumonia. Some pleuro-pneumonia. Several cases followed whooping-cough, others measles. Three cases occurred in asthmatics. Two were followed by pulmonary abscess. Acute or chronic cardiac diseases occurred in connection with many cases. Two were complicated with jaundice; in each instance the jaundice appeared on the fifth day of the pneumonia and was followed by a sudden and unexpected drop in the temperature with rapid disappearance of the pneumonic consolidation. Contrary to the opinion of some authors, that jaundice is always a fatal complication, both of these patients recovered. Of the one hundred and twenty cases relapse occurred in one abortive case and in one which ran its full course.

Of the two fatal cases, the first was that of a child two years old, whom I had treated the year previously through a run of pneumonia. In her second year, while suffering from whooping-cough, she developed measles of a severe type, an epidemic of the latter disease prevailing. With the measles she had a general bronchitis and then a double pneumonia. This little patient lived six miles away, at a time when the roads were almost impassable, and daily visits were sometimes out of the question. She struggled on to the ninth day of her pneumonia and died. I sincerely believe that had she had good nursing and constant medical attendance she might have recovered.

The second fatal case was that of an old lady, seventy-nine years of age, with a feeble dilated heart, rheumatic endocarditis, and general dropsy. I saw her some weeks previously to her pneumonic attack and sent for the priest at the time, as her pulse was feeble, irregular, and intermittent. She would not take medicine for her cardiac trouble, as she said she wanted to die, having outlived her usefulness. She would not have a nurse. She took the pneumonic chill one Sunday several weeks later. I saw her for the first time in this trouble on the Wednesday following. When I arrived the patient was dying. This patient died really of cardiac disease which ran on to its legitimate conclusion, owing to the fact that neither threats nor persuasion could induce her to take her medicine or any reasonable precautions.

In the whole series the plan of treatment was fairly uniform and it had at least the merit of simplicity. Comparatively few drugs were used, and the chief reliance was placed on free and long-continued diaphoresis. The history of an ordinary attack of pneumonia is that of a sudden chill with internal congestion, the chill being more constant and severe than in any other acute disease, and a rational treatment is to bring the blood again to the surface and equalize the circulation. The routine treatment was as follows: the patient was put to bed: four or five bricks were heated hot, dipped in hot water, wrapped in dry cloths, and placed around him: he was then covered with blankets and kept in a profuse perspiration for from four to forty-eight hours, depending upon the effect of the

treatment. If the temperature went down to normal, he was allowed to dry off slowly. He was not dried off with a towel nor permitted a change of linen. I considered it wiser that the patient should lie in the wet clothing until the temperature was normal, not only to guard against exposure to the air, but because the wet clothing assisted in reducing the fever by evaporation and conduction. The principal reduction in temperature was, however, undoubtedly effected by the diaphoresis, for with the occurrence of the latter the fever fell, the patient breathed easily, and the pneumonic process subsided.

As mentioned in a preceding paragraph, sixty-seven of these cases were aborted. A large proportion were seen reasonably early, with the result that they had a normal temperature, freedom from pain and cough, and easy respiration in a few hours; others yielded only after two days of sweating and a mercurial purge. I am fully convinced that many cases which ran their full course would have been jugulated had the treatment been instituted early enough and faithfully adhered to. In the absence of a nurse it was often difficult, at times impossible, to have the treatment properly carried out with young children and with refractory patients. Human nature seems prone to attach more importance to the administration of drugs than to the other equally necessary measures, and frequently the sweating was not thoroughly done though the medicine was given exactly on time.

If treatment was begun early enough, say within twenty-four hours after the inception, the disease was usually aborted readily. Occasionally it could be cut short when the lungs were completely consolidated and the brick-dust sputum copious. Typhoid pneumonias and pleuro-pneumonias alike yielded.

Free diaphoresis counteracts the effect of the chill by its action on the vasomotor system, bringing the blood to the surface. The cutaneous vessels dilate; internal congestion is thereby relieved; effete matter is thrown out; the volume of the blood is diminished by the water poured out through the skin, amounting to a very considerable quantity, as a rule; and the normal circulation is restored. In internal congestions the action of diaphoresis is in many respects similar to that of venesection.

More than this, diaphoresis is pre-eminently *the* antipyretic in pneumonia. In these days, when coal-tar antipyresis is being condemned and hydrotherapy lauded, we are in danger of overlooking nature's great antipyretic—not cold baths, but free perspiration. A moment's reflection, particularly on a warm July afternoon, will convince any one of this. Dalton, in his "Physiology," says "the most direct and simplest means of moderating the temperature of the body is that by the cutaneous perspiration." Michael Foster also states that "the great regulator (of animal heat) is the skin; . . . any action of the vasomotor mechanism which by causing dilatation of the cutaneous vascular areas leads to a larger flow of blood through the skin will tend to cool the body." Theoretically it is unnecessary to elaborate this idea. We are all familiar with it; in this all physiologists are agreed; but in practice many of us overlook it. When we induce perspiration in pneumonia we do much more than reduce the temperature in nature's own way, and, important though this be, the good effect is largely due to the circulatory changes induced.

Drugs played but a small part in the treatment. Quinine was given at times; also Dover's powder, to assist in promoting perspiration and for the moral effect; occasionally hot drinks until diaphoresis was established. So far as my observations go, simple diaphoresis by vapor baths was as effectual as when resultant from the use of drugs, and in my judgment quinine did not produce antipyresis except by the

diaphoresis induced. In other words, the temperature was reduced in proportion to the amount of perspiration it caused, not in proportion to the dose, and the statement of Bartholow, that in acute febrile disorders quinine reduces temperature by depression of the heart and arterial tension, by suspension of the oxidizing power of the blood, and by the inhibition of the white corpuscles, was not borne out.

I think this general law holds true, and explains the action of Dover's powder, veratrum viride, aconite, acetanilid, phenacetin, and many other drugs used in pneumonia, including carbonate and muriate of ammonium, which according to the older writers are good diaphoretics. Even tartar emetic is a powerful sweater under favorable conditions (W. H. Thomson, Pereira, etc.). We have most contradictory reports regarding some of these agents. Some physicians obtain remarkably good results from them; others say they are useless or injurious. Conscientious observers do not knowingly misrepresent these matters. It is altogether probable that the good effects of veratrum and aconite, for instance, are not due to the reduction in pulse so much as to their diaphoretic action. Acetanilid and phenacetin seem to have been used successfully at times. It is possible that the profuse sweating characteristic of the action of the latter drugs in fevers may be beneficial in the early stage of pneumonia, when the heart is still vigorous, but they are treacherous agents.

All these remedies, it will be remembered, are diaphoretics, vigorous diaphoretics. Ellis says, in regard to pneumonia, "when perspiration occurs and the pyrexia is manifestly less, I discontinue the aconite;" and Ringer states, in speaking of this drug, that "if the aconite is given at the earliest stage, when the chill is still on the patient, the dry, hot, and burning skin becomes in a few hours comfortably moist, and then in a little while is bathed in a profuse perspiration, often to the extent that drops of sweat run down the face and chest. With the sweating comes speedy relief from many of the distressing symptoms." If one physician gives aconite for pneumonia, or veratrum in full doses, keeps his patient lightly covered in an airy apartment, while another with the same drug and identical dosage keeps his patient hot-poulticed, wadded with oil-silk jackets, and swathed in blankets with the room at 75° F., it would be absurd to expect similar results. The drug administration would be the same, but the methods of treatment would differ radically.

Poultices I do not use as a routine treatment, believing that the benefit resulting from their use is largely on account of the local dilatation of the cutaneous vessels and the diaphoresis promoted by their application. That they do good is not denied, but I believe that the general application of moist heat is infinitely superior to the local. Poultices also necessitate in their renewal more or less exposure of the patient while in a profuse sweat, a matter certainly troublesome to the patient, possibly hazardous. Moreover, the use of poultices for days at a time all through a pneumonia, until the skin over the chest is soggy and sodden, while the circulation becomes sluggish and the skin water-logged, is certainly illogical and injurious. As a local application for the relief of pain I use them occasionally, but this is seldom necessary, since the pain is usually assuaged as soon as free sweating is established.

In regard to the prostrating effects of the sweating, so far as my experience goes, I can testify that this prostration has never been sufficient to cause the least anxiety. In no case was there collapse. The patient sometimes complained that he felt weak, but also "complained" that he was much better. A weakness from sweating is a form of depression from which recovery is astonishingly rapid, and is surely less seri-

ous than a weakness from fever or from an obstructed pulmonary circulation. It is obvious that the elimination of effete material from the system is not harmful and the loss of water is replaced in a few hours. In this connection it is well to note that the natural way for a pneumonia to terminate is by a critical sweat. Critical sweats are common, too, in intermittent fever, typhus, relapsing fever, and other diseases, and with these crises comes a marked improvement. If nature's method of regulating the body heat is by the sudoriparous glands, surely this treatment is not irrational.

When the pneumonia did not abort, the patient was kept in a moderate perspiration all the way through the pneumonic attack; fluid diet of a light nature and moderate in amount was given as the patient required it; no opiates, as a rule. Calomel, if the liver was inactive, was occasionally given in the ordinary doses and free purgation favored, not losing sight of the fact that certain cases of pneumonia naturally end by a critical diarrhœa.

Strychnine was often used and proved extremely efficacious in the later stages. Some maintain that strychnine acts directly on the right side of the heart, and if this is so it seems strongly indicated. Certainly this drug is a most useful remedy in pneumonia as a reliable cardiac stimulant.

Digitalis was given also in certain cases when it seemed to be indicated. With the mammoth doses now advocated by some writers, I have had little experience. In two cases in which this remedy was pushed vigorously alarming symptoms appeared, and its general use in large doses was discontinued.

The ammonium salts, carbonate and muriate, were frequently given in the cases which were not aborted, in small doses frequently repeated. These ammonium salts moisten the skin, promote expectoration, are claimed to prevent fibrin formations, but more than all are excellent cardiac stimulants; and I have found them useful and reliable agents in this disease. Iodide of ammonium was usually prescribed if resolution was slow.

Alcoholic stimulants were not used, as a rule, but when necessary were given freely. When the first sound of the heart resembled the second in character they were given, and in alcoholic subjects full stimulation was resorted to. In the case of the aged, alcohol was also employed.

Loomis states that pneumonia in the aged is usually fatal. "After sixty, the prognosis is always unfavorable." Of my cases twenty-four were sixty years of age or over, while ten ranged from seventy-five years up. Of these aged patients the one referred to died. In the old, circulatory disturbances are more serious; the vessels being inelastic, collateral and compensatory circulation is not so readily adjusted, and disturbances of the vascular mechanism not so easily equalized. In pneumonia, too, the rule holds good that "a man is as old as his arteries."

In treating these cases, the condition of the circulation was shown by the pulse, and the heart sounds were carefully watched and taken as a guide; the temperature range was considered of minor importance except as indicating the necessity for free diaphoresis if it rose too high. The diagnosis having been carefully made in the beginning, frequent examinations of the chest were avoided, as productive of evil and of slight benefit in furnishing indications for treatment. The heart and the pulse can be readily watched in pneumonia without changing the patient's position, without exposure to the air, and they furnish indications of more value than the pulmonary physical signs.

When cyanosis appeared, even vigorous stimulation usually failed to relieve it. The blueness of the finger nails and general duskiness are evidences of the

right heart's choking from overdistention, and since in this condition it is full to overflowing and the left is comparatively empty, the reason for the comparative failure of general cardiac stimulants is fairly clear. Stimulation is not required for the left heart, but the right has been laboring hard and is overburdened. It needs relief from its load more than the use of the whip. When cyanosis occurred, I bled if possible, then gave cardiac stimulants.

This opens up the question of blood-letting in pneumonia, one that is of late being revived by several earnest advocates of venesection in this disease. Is bleeding ever nature's method of treatment, and if so are we ever justified in following nature's lead? I have frequently heard old physicians, men of ripe judgment, say that they never saw a remedy so prompt and effectual in full-blooded patients with pneumonia as bleeding. I have heard an eminent professor of practice in a medical college, a distinguished clinician, state that he would bleed for pneumonia if he dared. If bleeding is indicated in a pneumonic case, if epistaxis occurs in a full-blooded man in the early stage of the disease, why not dare to bleed? Should we follow public opinion or lead it?

I resorted to venesection in a case of pneumonia for the first time when a hospital interne. The patient was a thick-necked, red-faced, plethoric young fellow. The diagnosis was confirmed by admittedly competent men. I bled him and the next day he was walking about the ward. Since that time phlebotomy has been employed by me on numerous occasions in the early stage of the disease. All cases are not adapted for this practice; there are prejudices to overcome, and free diaphoresis is amply sufficient in the average case to accomplish the same results; but my success with venesection in the congestive stage has always been highly satisfactory.

For nearly a dozen centuries blood-letting was in vogue, the old doctors maintaining steadily, with a perseverance and consistency during all these years which was certainly remarkable, and which in these days of rapidly shifting medical fads must excite our admiration, that venesection relieved pain, reduced fever, moderated the force and slowed the action of the heart, removed morbid material from the blood, lessened its volume, and reduced inflammation. Today a few of us still apply leeches and use dry or wet cups occasionally to accomplish the same ends. Is Hahnemann such a bugbear at the present day that we should feel our courage oozing out at our finger tips? If blood loss were so fraught with evil consequences, our surgical operations would have a higher mortality and each full moon would fill our churchyards.

The old writers maintained also that of all diseases in which phlebotomy was indicated, and in which the most positive results could be expected, pneumonia stood undeniably first. Are we professionally the descendants of a lot of fools? Were our grandfathers deluded and deceived, going on day after day, year after year, century after century, letting blood with a foolish and germless idea that they were doing good, without ever seeing any beneficial results from venesection? Is it possible that all the clear-headed thinkers, all the good observers, all the logical reasoners which ever adorned the medical profession, were born in the latter half of the nineteenth century, or may it not have been that the occasional good effect was so prompt, so marked, as to be beyond dispute, misleading those of the older generation into using the lancet too often? Blood-letting, like all great heresies, was founded on a half truth, and the men who wrote the constitution were not dunces, if the Monroe doctrine was as yet unknown; so, too, their medical contemporaries may have been able to give us some

pointers in the absence of all knowledge of antirabic inoculation.

The MEDICAL RECORD, of September 28, 1895, in commenting on the treatment of this disease by Dr. De Duplaa de Garat, who bleeds in his pneumonia cases, says: "Instead of burying all his pneumonia patients, the writer claims that he cures them all without exception." Can we afford with a mortality of twenty to forty per cent. in so commonly prevalent an affection as this to be even mildly sarcastic about the "claims" of one who advocates some other practice? Would it not be wise to investigate the matter, and ascertain if his claims are true to fact on the one hand or mere impudent effrontery on the other?

It is the common opinion of common people, most of them reasonably familiar with this malady and some of them possessed of fair powers of observation, that "pneumonia goes hard with big, strong, healthy men." The old family doctor, too, will tell you that such a person is "a bad subject" for pneumonia. He may not explain just why, but he has learned it by experience. Anæmia is common enough in these days, but is plethora never encountered? Frequently a deficiency, but never an excess? Bleed these patients, the full-blooded ones, in the early stage and they are no longer bad subjects for a pneumonic attack. Fail to do this, nourish them well, give them a full "supporting" treatment for a few days and a liberal proportion will die with blueness of the nails and general cyanosis.

There comes a time, too, when certain other cases require venesection, some plethoric, some not. When cyanosis develops during the course of the disease it is usually considered a very unfavorable symptom. Upon its appearance many physicians make it a rule to warn the friends that a fatal termination is to be expected. It is an indication of insufficient oxygenation and approaching venous stasis. The patient is practically beyond the reach of medicine, and yet is his case really hopeless? Is there no relief?

In this condition, when the "swelling of the veins of the hands," which Trousseau noted as dangerous, may occur; when the portal and hepatic veins, the vena cava superior and inferior are distended; when the sound over the pulmonary valve becomes indistinct; when the right heart is choked and dilated, open a vein and bleed freely or the chest will get "rattly," despite resort to drugs and stimulants, the blueness will increase slowly but progressively, and paralysis of the right ventricle will result. Bleed until the congestion under the nails perceptibly diminishes. Then give cardiac stimulants, and the right heart, relieved of its distention, able once more to approximate its valves, goes to work with renewed energy and the danger is for the time over. The pneumonia is not cured, but the pressure has been taken off the weak point.

Phlebotomy has been a pronounced success according to my experience in what were otherwise apparently hopeless cases. "Tying off" the limbs has failed with me as a substitute in the few cases in which it was tried. Cyanosis usually develops on the fifth or sixth day and even a temporary relief will often tide the patient over the critical point. Undoubtedly, it weakens him, but it is better to be hydræmic and living than full of coagulated blood and cold. We frequently meet with epistaxis at the crisis of a pneumonia. Can we not take a lesson from nature? It is evident that the letting of blood must diminish the congestion of the part of the lungs not affected by the pneumonic process. It also seems clear that lessening of the accumulation of blood in the right heart must diminish the labor of the lungs, since all the blood must pass through the lungs after leaving the heart, before it can be distributed to the remainder of the body.

Venesection is often necessary when cyanosis is present, even though the pulse is small and weak, for, the pulmonary circulation being obstructed, the left ventricle with the arteries is practically empty, and I have seen a pulse, weak and fluttering, come up strong and full while the blood was still flowing from the arm. This is explained by the lightening of the load of the right heart.

In the Massachusetts General Hospital Report it is shown that in the decade following 1822 the mortality was only ten per cent. This was the period when blood-letting was practised. It is now twenty-eight per cent. The difference is attributed to greater age, intemperance, complications, and a larger proportion of foreigners. How much influence the greater age may have had I cannot determine, as the original report is not at hand. It seems difficult, however, to prove that complications were really more frequent, and if this were true it might be attributed with some show of reason to difference in treatment as well as to other causes. Were there no alcoholics in 1822-32? Are foreigners so peculiarly liable to develop and to succumb to this disease that the fatality should be increased nearly threefold? Osler maintains that, "contrary to the general rule in infectious diseases, newcomers and immigrants seem less susceptible than the native inhabitants." Are these factors, even if proven, sufficient to account for the difference? Those old doctors must have had a marvellous streak of luck in their favor if blood-letting is so injurious. They certainly had no oxygen cylinders and no knowledge of the pneumococcus of Fraenkel.

Beverly Robinson in the *MEDICAL RECORD*, June 2, 1894, says: "Cases still occur where bleeding is the only resource." Dr. William Watt Kerr and Dr. Washington Ayer, of San Francisco, advocate venesection in the third stage (*MEDICAL RECORD*, June 23, 1894). Osler strongly endorses bleeding in the early stage, and while his results with venesection in the later stage (twelve cases) have not been wholly satisfactory, he considers it "a rational practice." Numerous other writers endorse this view, and last, but not least, Dr. Jacobi, in that much-quoted paper, "Non Nocere," says: "The pneumonia which, when delirium, cyanosis, and dilatation of the right heart became urgent dangers, was not relieved by a venesection . . . must be a load on the practitioner's conscience." This is well put. Is the pendulum on the return swing?

In conclusion, I would enter an urgent plea for a reconsideration of the etiology and treatment of pneumonia: for a more careful and systematic study of the changes which occur in the lesser circulation, pulmonary artery, capillaries, and veins, including also the bronchial vessels: for the use of diaphoresis as a rational and conservative mode of treatment, as a safe and powerful agent for the purpose of aborting pneumonias, and as an antipyretic of remarkable efficacy: for a more general recognition of the fact that failure of the right heart is the usual cause of death: and for venesection in certain cases of pneumonia in the early stage; also in the late stage when it becomes imperative, or as a *dernier ressort*.

Urination after Labor.—1. Urination after labor, in the majority of cases, follows spontaneously. 2. Catheterization is but exceptionally required: if it be necessary, it should be deferred as long as possible. 3. It is only indicated when the bladder assumes abnormal proportions, or if retention occurs. 4. Catheterization is liable to occasion two evils—cystitis, in spite of all precautions, and dependence of the bladder for a time upon the catheter.—*Rev. International d' Bibliog. Méd.*

COLONIES FOR EPILEPTICS.¹

BY FREDERICK PETERSON, M.D.,

NEW YORK,

CONSULTING NEUROLOGIST TO RANDALL'S ISLAND HOSPITAL FOR IDIOTS; CLINICAL PROFESSOR OF INSANITY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; CHIEF OF CLINIC, NERVOUS DEPARTMENT, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; PRESIDENT OF THE BOARD OF MANAGERS OF CRAIG COLONY.

THE moral treatment of epilepsy has scarcely as yet found its way into the text-books. In the most recent works on neurology we are informed that the disease is almost incurable, and a bewildering array of drugs, which may or may not be of benefit in some cases, is presented in considerable detail. But the enormous progress of therapeutics of epilepsy in the direction of moral treatment has found as yet no place in such works, even though the importance of this treatment is in the present state of our knowledge vastly more significant as regards the welfare of the patients than the pages devoted to medicinal agents.

Epilepsy is one of the most common of nervous disorders. It afflicts one to two in a thousand of the population. It is also a malady not at all new to the profession, for it was undergoing therapeutic experiment at least three thousand years ago in India and elsewhere to our certain knowledge.

Possibly ten per cent. of all cases of epilepsy become insane, so that they require the custody of an asylum. The remaining ninety per cent. are the cases under consideration in the present paper. This disease differs from other diseases in that it consists of periodic attacks of loss of consciousness, with or without convulsions, lasting, as a rule, for but a brief space of time—a few seconds to a few minutes. Before and after these short seizures the patient is in as normal a condition, and quite as capable of pursuing the ordinary vocations of daily life, as other people. In some the attacks recur frequently, several times daily, but these are uncommon; in others they recur several times a week; and again in others occasionally during a month or several months. But, however infrequently such seizures take place, the unfortunate sufferer from epilepsy cannot be permitted to attend school, go to church or entertainments, or play with other children, and as he advances in age he finds himself debarred by his malady from following any occupation, for no one will employ him. Naturally, a life of this kind closes to him the usual avenues for mental and moral development, and it is not surprising that many an epileptic who under other conditions might acquire a good education, be able to sustain himself by his own efforts, and even bring out talents of a high order (such as have distinguished a number of epileptics familiar in history and literature), should grow up feeble-minded and ignorant and an easy prey to all of the degenerative tendencies which are prone to show themselves when a mind is left to follow, unguided and uncared-for, its own instincts, appetites, and emotions. It is because of their neglect and ill treatment by communities that such large numbers of epileptics have been forced to seek a refuge from their woes in the almshouses and insane asylums. There has been nowhere else for them to go.

It is nearly fifty years ago since John Bost began near Bordeaux the system of caring for a variety of chronic cases, inclusive of epileptics, in cottages, grouping them in little families, feeling that the true home for such dependents is in the country, where they may occupy themselves in the gardens and fields, breathe the pure air, drink in the sunshine, and have before them always the works of their Creator. The little families grew into a prosperous and happy community, or, in other words, a colony.

¹ Read before the American Academy of Medicine, Atlanta, May, 1896.

About thirty years ago Pastor von Bodelschwingh began with four epileptic patients a similar family life in the suburbs of Bielefeld, Westphalia, Germany; and year by year the families have increased in number, until now the Bethel Colonie is a village of two or three thousand inhabitants, pursuing all the occupations and enjoying all the recreations of a thriving and prosperous settlement. In the winter of 1886 and 1887, while physician at the Hudson River State Hospital for the Insane, where I had become familiar with many of the troubles and misfortunes of epileptics, I made a tour of Europe for the purpose of examining various institutions;¹ and in the course of my journey I visited the colony for epileptics at Bielefeld, which made so deep an impression upon me that immediately upon my return home I wrote a description of it for a medical periodical in New York. I had never seen an eleemosynary conception so nobly and so successfully carried out. The good pastor of the Lutheran church who inaugurated this work will never be forgotten, so long as there are unfortunates to profit by his wisdom and benevolence. Here he created an ideal refuge for a multitude of sufferers, a home for such as were homeless or neglected, a hospital for the best treatment of their distressing malady, a school in which the education denied them in the outside world could be achieved, an industrial settlement for all who were able to acquire a knowledge of any trade or calling.

Since my visit many travellers have been there and have borne witness to the marvellous success and prosperity of this inspiring colony. I need refer to the testimony of but one of them, for in the deservedly popular volume entitled "A Colony of Mercy,"² Julie Sutter has described it in full with a felicitous pen.

One of my early papers on the subject of the colonization of epileptics was reprinted in England some years ago, and a knowledge of the subject diffused there by Miss Louisa Twining, and in Great Britain there are now two or three homes for epileptics, small beginnings of what are destined to be, no doubt, in future time, institutions or colonies of considerable size and importance.

France, Holland, Belgium, and other continental countries have also turned their attention to this class of patients, and are following more or less closely the good example of Germany, which has now a number of colonies for epileptics, in addition to the model settlement in Bielefeld.

In this country, Ohio, New York, Pennsylvania, Maryland, Massachusetts, Michigan, Wisconsin, Iowa, Illinois, New Jersey, California, Minnesota, Texas, and Virginia have either already established special institutions for epileptics or are actively preparing for it, to judge from the amount of correspondence I have had with physicians and others in these States interested in provision of this kind. The tendency with most of them is to follow as far as possible some more or less efficient scheme of colonization. But it is not always easy to establish and develop an institution, according to the most approved model, under the authority and at the expense of a State. Legislatures are only too apt to encourage, on the ground of economy, the housing of as many patients as possible in large barrack-like buildings, while the communities in which State institutions are about to be established are too frequently misled by local pride to demand something so colossal and monumental as to strike at once the beholder's eye. While it is true of many public institutions that it is more economical to house a large number of patients in one building than in cottages, it is perhaps less so in respect to epileptics,

since they are for the most part able-bodied and efficient workers, and their labor tends to more than make up for the increase in the complexity of administrative detail. But even were this not true, it is as much the duty of the State to lighten the burden of misery for a class afflicted with one of the most dreadful diseases, as it is to provide for their mere sustenance and protection from the elements.

I believe that in most States it will be found advisable to begin such provision in a moderate way with a large farm and two or three buildings, and to permit the colony to follow a natural course of evolution, as justified by its success and by the number of available patients.

A great deal of interest, both in this country and abroad, has been manifested in the undertaking of the State of New York to provide an industrial village for its dependent epileptics, not only because Craig Colony has become well known as the first real colonization plan begun on this side of the Atlantic, but because of the magnitude of the enterprise. It was necessary that provision should be made for a large number of patients, for the epileptic population of the State is great indeed, as will be seen from the following statistics: According to the admirable report of Dr. Charles S. Hoyt, superintendent of the State and alien poor, published December 31, 1895, there are in the county and city almshouses, 427; in institutions for the feeble-minded, 152; in other charitable institutions, 109; and in family care, receiving public outdoor relief, 83 epileptics. But besides these, there are in the State asylums for the insane about 1,000 epileptics, of whom, at the least estimate, fifteen per cent. are perfectly able to live in the freedom of colony life. I make this assertion based upon the statements of several of the superintendents of the said asylums. Not only have many sane epileptics been sent to asylums in the past, because there was nowhere else for them to go (except to the county almshouse), but the recent passage of the State care act led to the transfer to asylums of many epileptics, who had previously lived for a long period in the almshouses without any difficulty. This transfer was economical for the counties, and commitment for insanity in the case of epileptics is not a difficult matter, while the State was thus made to bear the burden of their care. Moreover, letters have been received by the managers of Craig Colony from over one hundred epileptics, not in institutions, but eking out some sort of pitiable existence in the outside world, among poverty-stricken relatives or on the support of charitable friends. Thus the number of epileptics immediately available for the purposes of colonization are: Epileptics in poorhouses and other institutions, and receiving public outdoor poor relief, 771; fifteen per cent. of the epileptic population of the State hospitals for the insane, 150; dependent epileptics without means, but not in institutions, 100. Whole number, 1,021.

This total of ten hundred and twenty-one epileptics falls short of the actual number in the State of New York who will ultimately become residents of the colony, and who are truly deserving of being beneficiaries of the State. In my service of eight years in the nervous department of the Vanderbilt clinic of the College of Physicians and Surgeons, nearly nine hundred epileptics have been under treatment there, the most of them without occupation, unable to gain a living, and supported by hard-working and struggling relatives. This is an experience in but one out of the thirty or more dispensaries of the city of New York, and in but one of the large cities of the State. It seems to me safe to say, therefore, that the number of indigent epileptics throughout the State who merit the care of Craig Colony is not overstated when it is placed at one thousand, making a total of over two

¹ "Some European Asylums," American Journal of Insanity, July, 1887.

² Published by Dodd, Mead & Co., New York.

thousand. Such statistics proved the need of projecting the scheme of colonization in New York on a large scale. The plan was favored, too, by the circumstances which led to the acquisition of a great tract of land. Not even Bielefeld has so extensive a property, and there is probably no eleemosynary institute of any kind anywhere in the world with landed possessions so magnificent. The Craig Colony had, in fact, already been a colony for fifty years or more, for the sect of so-called Shakers selected, with their customary sagacity, nearly nineteen hundred acres in the garden valley of the State (the Genesee Valley), and made it a remunerative property, with well-cultivated fields, fine orchards, and pastures and productive market gardens. They constructed here numerous substantial buildings (thirty or more), residences, barns, and shops; for they were not only thrifty agriculturists, but did a good business in broom making, canning fruits and vegetables, and other industries. On the grounds are good quarries of building stone, fine deposits of brick clay, and acres of good timber, from which they obtained materials for their houses. Two streams pass through it; one of them, rushing swiftly through a picturesque gorge and dividing the property into two nearly equal halves, ran the colony's saw-mill and flourmill.

But the Shakers, being celibates and failing to recruit their organization as in past times by proselytism and by the acquisition of orphan children, gradually diminished in numbers; and in 1892, at the time that the State was seeking a site for a colony for epileptics, the ten or twelve old Shakers left upon the place offered the entire tract with all its buildings for the purpose, at a sum (\$115,000) about equal to the value of the improvements alone. The State purchased the property, and the little band of Shakers went away to join the mother colony at Watervliet, N. Y.

Oscar Craig, of Rochester, then president of the State board of charities, was one of the commissioners engaged in the selection of the site. He died soon afterward, and at the instance of Governor Flower the colony is known by his name.

As soon as possible after the passage of the law establishing Craig Colony, the board of managers appointed by the governor began the work of adapting the old Shaker colony to its new purposes. Buildings had to be remodelled, renovated, and furnished, and systems of heating, lighting, water supply, and sewage had to be installed. In the neighborhood of ten or twelve buildings are at present occupied for the different purposes of the colony, cottages for the residences of the superintendent, farmer, engineer, steward, and other employees, three houses for patients, and several others for store, industries, and the like. In order to avoid any semblance to an institution on the pavilion plan, where doubtless the buildings would be designated as No. 1, No. 2, No. 3, or "A," "B," "C," and so on, each separate structure at Craig Colony has its own name. For instance, the superintendent's cottage is called "Sonojowa," an Indian word signifying hospitality. One of the first resolutions passed by the board of managers was to name the largest building in Craig Colony, used for administrative purposes as well as for patients, "Letchworth House," in honor of the Hon. William P. Letchworth of the State board of charities, who has been identified with charitable work for many years, who took an especial interest with Mr. Craig in selecting the site for the epileptic colony, and who has shown a keen sympathy with the work of its development. The old chapel of the Shakers, for so many years the centre for the gatherings of the elders and their brethren, now metamorphosed into a villa with a solarium for men patients, has been named in honor of its former

owners, "The House of the Elders." The farmer's house is designated as "The Grange." The steward's cottage, occupied by the steward's family and several officers and employees, was named "Tall Chief Cottage" after the Indian chieftain who in the old time called this particular tract "Sonyea," meaning the warm or sunny place. Sonyea is now the name of the post office of the colony and of the station of the W. N. Y. & P. R. R. on the grounds of Craig Colony. The colony has its own post, express and telegraph offices, and, besides the railway station already mentioned, the Erie Railroad has a station on the grounds, and the Delaware & Lackawanna trunk line passes within a quarter of a mile of the colony. Other buildings have been named "The Elms," "The Store," "The School," and so on. The present legislature is expected to give us an appropriation for a hospital of twenty beds, a mortuary, farmhouse, and funds for remodelling, renovating, and furnishing a half-dozen of the old buildings already on the tract, for the use of another hundred patients. The group of buildings now occupied is lighted by electricity, and the system of intermittent filtration was adopted for sewage. The water supply is excellent, springs being made use of for drinking and culinary purposes, the creek water for toilet, fire protection, etc. Rain baths have been introduced.

Very soon after the managers took charge of the property, the Messrs. Olmstead, Olmstead & Eliot, of Brookline, Mass., were engaged as landscape architects to prepare a general design of the grounds, in accordance with the organic law requiring the adoption of a general design and the arrangement of the property on the village plan, to which all new and old buildings must conform. Such a plan takes two or three years to perfect, but the main features, such as the village green, streets, lanes, paths, sites for shops, residences, chapel, dairy and farm buildings, schools, and the like, have now been designed upon the best principles, in order to take advantage of the natural beauty of the land, its gorge, lake, streams, hills, meadows, and woodlands, and at the same time to subserve as far as possible economy of administration and general utility. The details in the execution of such general design are to be worked out under proper guidance by the patients themselves.

Craig Colony was informally opened nearly four months ago. It has a present capacity for two hundred patients, and the provision for new patients will be gradually increased year by year. The present residents of the colony have been taken from the almshouses of the various counties in proportion to the epileptic population, and as fast as they have been received they have been put at some occupation compatible with their conditions and in accordance with their wishes and abilities. It is the aim of the management to provide out-of-door employment as far as possible for both men and women, feeling that great benefit in the treatment of the disease will be derived from work in the sunshine and open air. Therefore, agriculture, horticulture, floriculture, and market gardening will form a large proportion of the labor of the inhabitants for at least six months of the year. The women will gain great good from employment in raising small fruits, flowers, and vegetables.

The deposits of excellent clay are to be utilized by the patients for making brick to be used in the construction of new cottages and of walks throughout the village lanes.

The dietary for patients afflicted with epilepsy is simpler than that needed for other classes of patients, so that almost everything in the way of food stuffs required by a large population can be produced from the land itself by the labor of the colonists. During the year previous to the opening of the colony, the

managers by renting out tracts of land on shares cleared seven or eight thousand dollars, which is evidence of its productiveness and of what may be expected of it when each acre is made to yield its treasures to the unremitting care and attention of the colonists. There is already a large flock of sheep, a goodly herd of cows, and other stock of various kinds under the care of the patients.

But in addition to these features which characterize it to a great degree as an agricultural and stock-raising settlement, numerous other trades and callings will need to be summoned into being with the gradual evolution of a self-supporting and independent colony. There must of necessity be masons, painters, carpenters, cabinetmakers, printers, bookbinders, smiths, tailors, shoemakers, and the like; and there will be plenty of indoor work for women in the way of sewing, tailoring, knitting, fancy work, illumination of mottoes, bookbinding, the preserving of fruits, vegetables, seeds, etc. Indeed, the aim is to diversify occupation in every possible way, to consult the patient's own wishes as to his or her special proclivities and abilities, and to make the labor not only of value from the economical standpoint, but also from the standpoint of therapeutics, for we feel that the exercise, the life out of doors, the manual and industrial training, and the mental occupation will best bring about the bodily and psychic conditions which conduce to improvement and recovery.

It has been found by actual experience in other colonies, and this is already borne out by observations at Craig Colony, that the number of attacks in most patients diminishes after entering upon such colony life; that the patients do not affect each other detrimentally, but that on the contrary each feels that he is on an equality with his associates and no longer isolated, for he is bound together with them by the ties of a common affliction and a common purpose. Out of the negligence, monotony, hopelessness, and often squalor of an almshouse or a wretched home, he comes into the brightness of this new existence. He gains fresh interests, and new hopes and ambitions rouse him from his long apathy. He is made to feel that he may follow the bent of his nature as regards education and occupation, and no longer be debarred from the opportunities for progress in mental development, for recreations and enjoyment, and for social intercourse, so abundantly offered his more fortunate brethren of the outer world.

In addition to the moral therapeutics thus outlined, it is the object of Craig Colony to make every effort to treat each case of epilepsy entrusted to its charge in the best manner possible, in accordance with the latest researches of science in this field, and to carry on original investigations, clinical, chemical, pathological, and therapeutical with the object constantly in view of discovering the causes of and best remedies for the malady. For this purpose chemico-physiological and pathological laboratories are in course of construction.

The colony is designed essentially for State patients, that is, patients upon public charge, but as soon as these have been provided for, private patients will be received whenever there are accommodations for them. There is no restriction as regards admission, except the single one of insanity. Insane epileptics are excluded. It is probable that in the course of time some sort of provision will be made in the colony for epileptics who become temporarily insane while residents, but that is a matter which has not as yet been given careful attention.

In closing I wish to outline briefly the main points which need to be considered in planning and organizing a colony of this kind. In the first place such a scheme aims to provide:

(a) A home for a class of individuals cut off all their lives from ordinary pursuits and social pleasures by a malady which robs them of their faculties in most instances for but a few moments each day, or week, or month, or once in a period of several months.

(b) A school. Debarred from the public schools, the epileptic should be given precisely the same opportunities of acquiring an education as he would enjoy if well and living in the outside world.

(c) An industrial education. The usual trades and callings of a village should be introduced, and each colonist should be permitted to take up any pursuit for which he seems best fitted.

(d) Treatment for epilepsy. Every case should be carefully studied and treated according to the best scientific methods.

Having in mind the aims of the colony, the following points should be kept in view in establishing it:

1. There should be an abundance of land, for the community is to be given largely to agriculture and kindred pursuits, and there is economy in securing a large and productive tract.

2. The site selected should be near the centre of population and convenient of access to the managers and patients and their friends.

3. The country-village idea should never be lost sight of, and everything savoring in any degree of "institution," "asylum," "pavilion plan," etc., should be avoided. A general design should be adopted, with system in the arrangement of the buildings, but no such symmetry as would in any way suggest a public institution. The cottages, villas, and shops should be simple, independent, and homelike, with their own little gardens, hedges, etc.

4. As far as possible, each home circle should be limited to ten or fifteen patients; much greater aggregations than this are apt to destroy the family character of colony life.

5. The houses need not be especially planned to meet the wants of a particular class of patients, but should be as much as possible like ordinary village houses, though fireproof.

6. A small hospital, say with twenty beds, will be needed to serve as an observation station for new cases admitted and for such as are bed-ridden from intercurrent illness or accident.

7. In addition to hospital, cottages, villas, shops, schools, etc., a chapel, library, museum, reading-room, gymnasium, swimming-bath, rain bath, lecture hall, and well-equipped laboratories should be provided. Some of these, being luxuries, may doubtless be obtained by private foundation as memorials.

8. In developing the industries of the colony, the first object is to establish such as will subserve economy. The aim should be to produce most of the food stuffs required, to make the wearing-apparel, to carry on domestic work, to make all ordinary repairs, and to lay out the grounds. As the industrial side of the colony increases in usefulness, the trained workers should plan, construct, and furnish completely all new buildings needed, and other industries should be undertaken which will lead to a profit to be expended in the interests of the colonists.

9. The educational features should never be lost sight of, and in addition to the schools and industrial training, everything that can in any way be helpful in furthering such purpose should be encouraged. The trees and flowers should be labelled with their names whenever possible, and a botanical and zoölogical garden be established, as far as commensurate with the means at command. The collection of objects in natural history for preservation in the museum should be a part of the recreation of the inhabitants, and there are many other features too numerous to mention.

here which will conduce to the success and prosperity of the colony.

10. Finally I would caution the promoters of such plans for the various States not to hurry their development, but from small beginnings gradually to evolve an institution which shall reflect credit upon themselves and their undertaking.

ACCIDENTAL GUNSHOT WOUNDS: A MEDICO-LEGAL STUDY.

By J. N. HALL, M.D.,

DENVER, COL.

MEMBER OF THE MEDICO-LEGAL SOCIETY OF NEW YORK, ETC.

IN order that one may properly interpret certain signs that may be found in the investigation of deaths from gunshot wounds, he should be familiar with the common causes of accidents in handling firearms. I shall omit any consideration of the fractures, bruises, and other injuries, many of which I have observed, caused by the recoil of the weapon, although this is by far the most fruitful source of injuries from firearms, because, obviously, they are not gunshot wounds. Many of the cases I shall quote would scarcely call for a medico-legal examination, because of the circumstances under which they occurred; but the study of them will none the less be profitable.

It is pretty well known that most of the accidents from the use of firearms occur from ignorance or carelessness in handling them. At times a gun bursts from a defect in the metal or from imperfect workmanship, but such an accident is rare after the rigid tests to which the barrels are subjected at the factory, or, in many countries, at the government proof house. Old weapons burst from becoming "burnt out" from long and hard shooting, occasionally, but probably not without the use of an excessive charge. Many guns are burst by the use of new powders, the effects of which, under different climatic and other conditions, have not been thoroughly studied. I have seen the head of a brass shell separated from the rim in using a new nitro-powder, apparently because the powder was subjected to prolonged heating, having been left in the left-hand barrel of a double gun on a hot Au-

gust day, while many charges were fired from the other barrel. An increased action in the same direction might well burst the barrel. I have several times seen a similar accident from the use of black powder so fine that its initial pressure was too great for the kind of weapon in which it was used, although the danger of bursting the arm from this cause is certainly much less than from the nitro-powders, which produce a much more sudden explosion. I have never seen an unobstructed barrel burst by a charge of black powder of reasonable size, although I have known many shotguns and one rifle of excellent make either burst or loosened at the breech by some of the nitro-powders.

The cases of injury to the shooter by the bursting of a barrel obstructed by sand, mud, or snow, or by pressure against the earth or a fallen animal in giving it its death-blow, are generally obvious enough, so that no question could arise as to their being accidental or otherwise. In one such case, in which a young man attempted to shoot a skunk which had taken refuge in a burrow, four persons were injured besides the shooter by the flying parts of the weapon, as reported to me by Dr. Hawes, of Colorado. It is notable in these cases that the charge itself does little damage, its force being dissipated in the act of bursting the barrel. The flying parts, chiefly of the ribs and barrel, are the effective missiles in such accidents. When the arm bursts from too great a load, the charge is more likely to be effective. In a recent case of mine, the boy who supported the muzzle of a gun which burst from this cause was nearly as much injured as the one at the breech, from the fragments of the barrel, but I could not learn what force the load had exerted in its proper direction, for both the boys were too badly hurt to note this point.

It should be noted that even the lightest snow in the muzzle will endanger the gun from the cause mentioned. The tompon used to stop the muzzle of the army rifle occasionally makes trouble, because of the soldier's having forgotten to remove it. With the heavy rifles used in hunting, there seems to be more danger of blowing parts of the breech mechanism back into or just over the head of the shooter. Thus, a companion fired a twelve-pound Sharp's rifle at a deer, after having by accident filled the muzzle with sand. The firing pin passed through his hat, but the barrel, which I afterward examined, was uninjured and was in use for years afterward. The shotgun generally gives way at the thinner parts near the muzzle or in the middle, although I have seen several burst near the breech by nitro-powders. About a dozen examples of bursting in shotguns from the various causes mentioned have come under my observation.

It should be noted that after a misfire, and especially after the shot escapes from a shell from the dislodgment of the top wad, as occasionally occurs, portions of the load, and especially the wadding, may remain in the barrel and may cause an otherwise inexplicable explosion of the weapon. The bullet itself may stick in old and foul weapons, the gases of combustion escaping at the rear, through ill-fitting breech parts. I have known several bullets to accumulate in the same barrel from this cause, both in a small rifle and an old revolver.

It is somewhat dangerous to discharge very old guns, because of the fact that repeated jarring may cause the molecules of metal to rearrange themselves in crystalline form, when they will stand much less strain than before. One of the old guns in the Tower of London, subjected for a long time to the jarring incident to testing arms in the same building, broke merely from falling to the floor. The tendency to such crystallization is well known to be one of the faults of cast-iron ordnance.

Slight obstacles and especially "leading" or accumulation of lead and dirt in the grooves of the rifle, often cause the gun to shoot "wild." This is especially true if the trouble is just within the muzzle. One might easily meet with an accident if shooting such a weapon, provided any one stood near the line of fire. Accidents in the shooting of the apple from the head, *à la* William Tell, several of which have been reported, probably occur at times from this cause, although in at least one instance the fatal result was attributed to faulty ammunition. A physician of my acquaintance informed me that he nearly killed a negro who insisted upon marking for him when trying a new rifle, because the sights were misplaced, the weapon shooting nearly five yards to the right at one hundred yards' distance. I have known many narrow escapes from injury from the various causes mentioned in this paragraph.

Many injuries occur in using breech-loading weapons from having the breech chamber so foul that the shell sticks, and the pressure of the lever causes it to explode. This happens easily if the firing pin does not work freely or if the primer be not seated well down in the cavity prepared for it in the head of the shell. Shells swollen from repeated reloading give rise to the same accident even more frequently, and especially when, in the presence of game, the shooter is especially anxious to shoot rapidly. I have recently seen three accidents occurring under such circumstances, and all giving the more or less characteristic staining of the face, especially of the right side, with a few grains of powder blown into the conjunctiva, a result commonly associated with this form of accident.

I have known the five loads in the magazine of a repeating shotgun to be discharged through the end of the tube, without damage to the shooter, from the accidental admission of sand to the rear end of the magazine. Probably the spring which forces the shells backward in reloading forced the primer of the rear one against a bit of gravel in the bottom of the magazine, causing it to discharge its shell, and then each shell exploded the one in front of it. Similar accidents formerly happened in the use of magazine rifles, from the temporary sticking of the spring from rust or other cause; becoming suddenly loosened, the spring pushed the cartridges backward over a greater distance than normal, because of the removal of one or two shells previously, and hence with unusual force, and the primer of one shell being struck by the tip of the bullet of the one behind it, an explosion occurred. This danger has been, I believe, entirely obviated by flattening the tip of the bullet, sinking the primer about a thirty-second of an inch into the head of the shell, and using brass instead of the softer copper for the primers of rifle shells, these primers requiring a stronger blow for discharge.

Accidents to the shooter are more common when the barrel is unusually short, for the reason that in event of a fall or slip such a weapon is brought to bear more easily upon the person of the one carrying it. I have known several injuries, chiefly to the feet and legs, from this cause. In two cases the great toe was shot off.

A great number of accidents arise from the slipping of the finger upon the trigger, or, more commonly even, upon the hammer, in attempting to cock the weapon or to let the hammer down. If the weather is cold, the fingers often become benumbed, so that the shooter is not aware of the contact with the part or else is unable to properly estimate the amount of force applied. If the fingers are wet or if a glove be worn, and especially if the latter become wet, the hammer often slips out from under the finger or thumb in handling it. If a hair trigger be used, as upon many

rifles, such accidents are very common, for the least touch fires the weapon. If any one be in range, or parts of the shooter's person, a wound results. Many shots at game are missed from the causes mentioned—I have missed several myself.

In wing shooting, I have known several narrow escapes from serious injury from swinging the shotgun, in following a bird, directly upon another shooter; and I have twice known dogs to be killed, once in this manner and once because the dog suddenly raised his head into the line of fire as the trigger was pulled. It is unsafe to hold the rein of one's horse when shooting, because a sudden pull may deflect one's aim and injure either the horse or another shooter. I treated one wound caused in this manner.

The foreman of a gang of cowboys, driving cattle from Texas years ago, took a violent dislike to a friend of mine, and rode up alongside of him on horseback, with a loaded shotgun across the saddle, the muzzle toward the latter. Suddenly the weapon was discharged, the load passing between the rider and the horn of the saddle. The foreman had previously killed a rider near Abilene, Kan., and undoubtedly intended to kill this one and have it attributed to accident. The rider took the hint that he was not agreeable, and left the outfit. I have no doubt that many so-called accidents have some such origin as this one had.

It is not uncommon for one to be injured in cleaning up an old gun supposedly empty. Thus, I know of one accident from inserting such a weapon into the fire to clean it more effectually, the owner holding it by the muzzle meanwhile. Attempts at removal of a "stuck" cartridge in a breech loader are often followed by explosion of the shell and injury by the bullet. The latter has but little penetrative force, however, if the shell be not firmly supported in the rear; and it is not commonly well supported in these cases, because the breech of the weapon is open. In one such case of mine, the ball from a small pistol did not penetrate the skin of the left thumb, the force of the powder being expended apparently in blowing the shell backward, and dissipated in the air about the open breech. I have seen many accidents from careless handling of loaded shells, as, for example, from the attempt to remove the primer of the shell before removing the powder, or setting the bullet in a rifle shell without placing the head upon a proper base, so that some solid substance came against the primer; but these cases are sufficiently obvious to the examiner.

The left hand of the shooter is at times injured in supporting a revolving weapon in front of the chamber, from the running of the fire from one chamber of the arm to the next. I have never known of such an accident in a weapon using fixed ammunition. Occasionally the old "pepper-box" pistol blew the hammer back and revolved the cylinder, as a result of the escape of gas through the nipple, so that two or three shots were discharged instead of one, as intended. Weapons of the kind mentioned here, however, have become nearly obsolete in this country.

Many accidents have happened from the use of set or trap guns, either for protection against burglars or in killing game. I have quoted elsewhere¹ a case in which a dog ran against a gun as it lay across a log, causing it to shoot the hunter, several feet away. Several cases are quoted in English works bearing upon this subject. In one case a fowl trod upon the trigger of a cocked gun, which the owner had left standing against a corn bin, and the man was struck by the load at a distance of several yards. In another case a dog ran against a gun lying upon the ground, and shot the brother of his master. Taylor mentions

¹ *Medico-Legal Journal*, December, 1893.

a case in which, in the attempt to put the cap on to the nipple of the second barrel, the first was fired, and the gun, from the recoil, jumped out of the hand of the shooter and flew back in such a manner as to fire the second barrel, the contents striking the man's body.

If either sight of a weapon becomes displaced, the bullet may easily strike one marking at the target, as previously mentioned, or supporting an object shot at. Near-sighted individuals, and even those with fair vision, at times mistake objects through the sights, and in that way shoot at the wrong mark. I have quoted elsewhere the case of an acquaintance who from this error shot through the clothing of the marker at the target.

I have read of three accidental shootings in this State, during my residence here, from mistaking a hunter for a deer. In two of them the injured man wore buckskin clothing, so that the color approached that of the game in question. It is needless to say that it is utterly unjustifiable to shoot at anything until its character is known. I have known a man to kill a donkey on the supposition that it was a mountain sheep which he had been following.

In the use of the rifle accidents often occur from the deflection of the ball by some hard substance with which it comes in contact. I have known a bullet to glance from the limb of a tree and become so much deflected upward that it went over the hill which was used as a butt for target shooting, and almost struck a man three-fourths of a mile away. A town marshal near this city shot at a dog across a city square, and the ball, glancing on the stone sidewalk, struck a passerby on the opposite sidewalk. The dog escaped. I have known a policeman to shoot at a dog tied to a stone wall, with the result that the ball glanced and struck the man in the foot. In another case the pistol ball glanced from the head of a dog and struck a young lady in the back of the neck, with serious but not fatal result. She stood some sixty feet from the dog. The latter animal was finished with a club. At Fort Russell, Wyom., about six years ago, a ball struck a nail head in the target, a part of it glanced downward, and the marker, being in the pit directly under the target, received this portion in the chest, dying shortly afterward. An instance was reported some time ago of a man who shot into an iron pot with a rounded bottom, with a pistol. It was stated that the ball glanced in such a way as to return and strike the shooter. Small bullets fired at a hardwood target from a revolver, with a very small powder charge, may rebound and strike the shooter, not penetrating the wood sufficiently to stick. Such rebounds may be entirely harmless, as I have experienced them on two or three occasions in making experiments, the ball not having force enough in rebounding to carry it more than the length of an ordinary room.

Hunters, in dispatching a fallen animal, occasionally in their excitement place the muzzle of the gun directly against it, and thus cause the barrel to burst. The effect of the shot in such a case is often nearly lost. Many suicides, from making a similar mistake, fail to accomplish their object, placing the pistol directly in contact with the body, with the result that the ball bruises the flesh but does not penetrate. At times it may fall almost harmlessly to the floor. I have quoted one such case in the *Boston Medical and Surgical Journal*, May, 1895, although not in the attempt at suicide.

The self-cocking revolver is the source of many accidental shootings. In one's excitement the trigger is almost involuntarily pulled, and, the weapon being short, it may be pointed either at the person of the shooter or at a bystander. One patient of mine shot himself in the foot through such an accident. Another,

carrying in his right-hand trousers' pocket a small revolver of the pattern mentioned, with his hand upon the trigger and apparently studying over the matter of how he would punish the man whom he was pursuing, unconsciously grasped the weapon too tightly and shot the bullet out through his clothing into the sidewalk, the powder burning his genital organs. A year or two later, the very man he was then pursuing and who owed his escape in part to this accident, in the attempt to strike an assailant over the head with a similar revolver, accidentally killed him, and was the subject of the case reported in the *Boston Medical and Surgical Journal*, August 14, 1890.

With cannon, and especially with the small ones used in celebrations, accidents frequently occur from the forgetfulness or carelessness of the person designated to "thumb the vent" in reloading. If the thumb stall be thin, the hot metal burns his thumb, and he withdraws it while the rammer is inserting the powder charge, causing an instantaneous discharge in certain cases. I have known of two serious accidents of this nature, one causing a death and the other injuring two men severely; while in a third, which occurred under my own eye, the rammer was but slightly burned.

It is not uncommon to have accidental injury from attempts to perform tricks with the revolver. I treated a man some years since, who, in trying to whirl his 45-calibre weapon around his finger, after tying the trigger back, and fire it at each revolution by catching the hammer with his thumb, succeeded in shooting himself in the leg. I knew of another similar accident which happened in the same region.

Where pistols are carried habitually, many persons are injured from the dropping of the weapon from the holster or pocket in mounting a horse or getting into a wagon, or in the attempt to draw the weapon quickly. One friend of mine shot his horse, on which he was sitting, from the latter cause. A friend reported to me an accident from the catching, upon the counter of a store, of the hammer of a revolver carried in the pocket, when the owner tried to lift himself up backward to sit upon the counter. The ball entered his clothing, but did no serious harm. A case has been recently reported, in which a man was kicked by a horse in the region of the hip pocket, in which he had a revolver. It was discharged and the bullet entered his leg. All of the injuries from catching the hammer which have come to my notice have been in the lower extremities, while those from the dropping of the weapon in mounting a horse or entering a wagon have been generally in a direction upward, and hence have been in the trunk at times as well as in the legs.

I have known of one case in which a man shot his great toe off, firing at a target at long range, having assumed the position so common in this sport, in which the barrel is rested between the knees as one lies upon his back. He had unconsciously stretched his feet out until one was in front of the muzzle. In another instance the shooter burned the toe of his boot in similar manner.

Many boys are wounded in the left hand with small revolvers and toy pistols, while holding the barrel in the left hand and attempting to dislodge a cartridge stuck in the breech chamber or to close the weapon under such circumstances. Many such cases show a pebble in the hand, this having been used in lieu of a bullet in a small pistol, over a blank cartridge. At the Massachusetts General Hospital, on the morning of June 18, 1880, following the celebration of the anniversary of the battle of Bunker Hill, I saw six such cases, and during the following two years many such cases presented themselves at the Boston City Hospital. At that time a particular variety of toy pistol, using a blank cartridge, was greatly in vogue among

the boys of that region. Five deaths from tetanus following such wounds occurred in one month during my service as house officer.

Many men have been injured in taking a loaded gun through a fence, or from a wagon, or out from under a tent or bedding in camp. It is commonly supposed to be empty or else the person handling it carelessly gets in front of the muzzle. Many accidents occur from riding behind a loaded gun in a wagon or buggy. Three fatal accidents and one non-fatal of these varieties occurred in a few years within a radius of fifty miles of the town in which I practised. One patient of mine shot himself through the body with a government rifle, in the attempt to draw it toward him as he sat upon the seat of his wagon. Many fingers are lost by holding them over the muzzle, or having them in contact with the cleaning-stick or ramrod when a shell sticks or a load misses fire and an investigation is being made. One patient of mine shot off his right forefinger, having held it over the muzzle while trying to shut the lever of his shotgun.

Many accidents have happened to poachers from carrying short weapons, which for concealment are carried in the pockets after being detached. A relative of an Irishman with whom I hunted one fall was killed in crossing a stone wall, by the charge from the barrels of a double gun which he had concealed in his coat-tail pocket. As he raised the tails of the coat to step over the wall, the barrels, which were muzzle down in the long pocket, fell downward, and the cap of one barrel striking on the wall, the charge passed upward into his abdomen. Several similar accidents are on record in English works.

In the struggle for a weapon with which one person has assaulted another, many injuries take origin. In one of my cases the revolver was discharged when held over the shoulder of the owner, and a fatal wound resulted, the ball passing through the heart. In a case which I saw with Dr. Parkhill, of Colorado, the bullet passed in a similar case through the left lung, and the patient recovered. The history given by the patient was that, in the attempt to shoot a highwayman in the night, the latter seized the weapon and pointed it at the chest of the owner, and it was discharged while in that position. In a Denver case, which I did not see, the pistol ball cut off two fingers of the woman who was trying to use the weapon upon a man employed about the ranch. One can easily see that any variety of wound might come from the very unusual positions in which a pistol might be placed in such a struggle. There can be little doubt, however, that at times suicide is attempted with an unsuccessful result, and that the intending suicide then tells a story of an attack upon himself by another, of his attempt to shoot the attacking party, and of a consequent wound from his own weapon. I feel sure that I know of one such case, for the injured man was known to be despondent over a love affair; but one shot was heard instead of three as he stated, and but one chamber of his pistol was empty. He claimed to have fired twice at the retreating highwayman after being himself shot in the scuffle; but there was no evidence outside of his statement that he had done so, nor was there evidence that any other person had been near him at the time of the shooting. In another case reported to the Denver police, a man claimed to have shot himself by accident. He had a wound of entrance on the rear aspect of his leg, and some bystanders had heard three reports, so that it was thought that his story was not true, but that for some reason he did not wish to have it known that another had been concerned in the shooting.

I have quoted elsewhere¹ the case of a man who drilled a vent hole in the end of the cast-iron sleeve which fits over the wooden axle of a wagon. When he

filled it with powder and fired it, it burst, and he lost his thigh as a result, being struck by one of the fragments, as reported to me by Dr. Hawes, of Colorado. In a recently reported case, a turntable bolt burst with fatal effect in a similar manner. These cases are, however, so common and so obvious, even to one not especially familiar with the subject, that I need not quote other cases.

Perhaps the most prolific cause of accidental shootings is to be found in the habit of pointing a weapon at another in fun, under the impression that it is not loaded. These cases are reported in every community with great frequency. In one case reported from Pocatello, Id., a Bannock Indian withdrew the charge from his muzzle-loading gun, and then tried it upon a brother Indian brave. Apparently a second load remained in the barrel, for he killed the object of his sport. Witnesses had seen him remove one load from the barrel in question. In the town in which I first practised, a cowboy showed his revolver to his sweetheart and shot her through the body through some unaccountable accident. Children learn to shoot toy pistols and are permitted to fire them at one another with impunity. Then, obtaining a revolver in some manner, they use it in similar fashion. In one of my cases, a boy of only three years shot an older one through the knee in this way.

Sheer foolhardiness is responsible for an enormous number of accidents. A friend of mine had his forearm shot full of bird shot as the result of his companion's trying a gun, which had missed fire many times, upon him. In one case I knew a boy to allow such a weapon to be fired at him at forty yards for twenty-five cents. Curiously, it failed to shoot—the only instance I have known in which a gun failed to do its work in such a case.

An acquaintance of mine followed a hunter through some thick brush, the latter's shotgun being over his shoulder. The trigger caught upon a branch, and the load passed over my friend's head. Many fatal accidents have resulted from just such causes.

One of the most frequent sources of accidental injury from firearms has been done away with very largely by the introduction of breech-loading weapons. With the muzzle loader, many people were hurt from ignorantly using an enormous load or from placing two loads in the same barrel. In one of the cases I have already quoted, two boys placed four inches of powder and thirteen leaden bullets in a shotgun, and were both injured by the explosion. The left hand is the one commonly hurt by the flying parts, from the position in which it is held.

If the shooter put the cap in position before loading, at times the powder flask or shot pouch would be dropped, and, striking the hammer, carry it backward far enough to allow it to strike the cap with force sufficient to fire the weapon, the charge often striking the head of the man loading it. Occasionally after the removal of the cap from the nipple, the gun being considered perfectly harmless, it was snapped at another person, and caused death. The explanation is that the white substance seen in the bottom of the inverted percussion cap, the fulminate of mercury, became detached and remained upon the nipple, being still just as effective as when contained in the cap. Accidents continually happened on loading the empty barrel with the other at full cock. In one case the hunter stood upon a log, after killing a rabbit, that he might watch for others while reloading. His foot slipped, the hammer of the loaded barrel struck the log, and the charge entered the man's abdomen. The jarring off of the second barrel in badly worn guns from the shock of the first commonly harms only the shooter, and then only by the recoil. The "hangfires" commonly do no further harm than to cause a miss, but obviously

¹ *Medico-Legal Journal*, December, 1895.

might be serious if one had changed his aim sufficiently to bring some one in range. Many accidents are quoted from the attempt to withdraw the charge of a double gun before removing the cap, or after removing it but leaving the fulminate in place.

Finally, I have known several accidental discharges of weapons from attempts of amateurs to change the action of the lock of the arm, and especially from filing away the notch holding the hammer in position at full cock, to make the trigger pull of the gun lighter.

Progress of Medical Science.

Corrigan's Pulse, it seems, should be called Vieussen's pulse, as he described it in 1715. According to Huchard, Corrigan's pulse is the "jerking," water-hammer pulse due to aortic regurgitation.—*Medical Examiner*.

Chorea.—Sir Dyce Duckworth (*Wiener medizinische Blätter*, xvii., 1894) says chorea is simply another variety of rheumatism, in which the brain is affected instead of the joints. He considers that the definition of Andrew Clark, "rheumatism of the brain," is very appropriate.

Dysmenorrhœa.—Dr. H. Talley (*Philadelphia Poly-clinic*) states that a mixture of caffeine, potassium bromide, and tincture of gelsemium is of much value in the treatment of dysmenorrhœa. This should be administered for a few days before menstruation.

Vomiting of Pregnancy.—The *Canada Medical Record* advises putting a blister over the fourth and fifth dorsal vertebra. Some writer is quoted as saying, "By a single vesication I have never failed to put an end at once to the sickness of pregnancy for the whole remaining period of gestation, no matter at what stage I was consulted."

Treatment of the Funis.—Dr. Abraham Jacobi (*New York Medical Journal*) states that in wrapping up the end of the cord oil must not be used, as moisture and the exclusion of air favor gangrene, while warmth and dryness favor mummification. Powdered bismuth subnitrate, zinc oxide, iodoform, or salicylic acid, one part with ten of starch, may be dusted around the stump daily. The latter is not useless as an antiseptic. The normal process of separation usually occupies from twelve to fifteen days, but careless handling, local irritation, and infectious influences may prolong the process for weeks. Under such circumstances local treatment is required. Carbolic acid should be avoided, as infants are easily affected by its toxic properties. Solution of lead, zinc, or alum answers quite as well. Dr. Jacobi recommends powders of zinc oxide, bismuth subnitrate, alum with starch, and salicylic acid with starch or iodoform. Neither iron perchloride nor iron sulphate should be used, as secretions will accumulate under the coagulum formed by its application.

The Arrest of Rheumatic Endocarditis.—Dr. Caton, in a paper read before the British Medical Association, urges the importance of a more active treatment of rheumatic endocarditis than is usually employed, with the view of arresting the disease if possible in its initial stages. As soon as any bruit is detected, a series of small blisters, each the size of a florin, is applied along the course of the third, fourth, fifth, and sixth intercostal nerves in front and at the sides. Only one is applied at a time, and the different exit points are covered consecutively. In this way the blisters give rise to no pain or inconvenience. At the same time sodium or potassium iodide, in eight or ten grain doses, thrice daily, is administered, and the

ordinary salicylate treatment is continued. Lastly, the patient is kept in hospital for six weeks, most of the time in bed. Under this treatment most of the writer's cases (twenty-nine out of forty) in which symptoms of acute endocarditis had supervened left the hospital with, so far as could be detected, a perfectly normal heart.

Effects of Lactation on Menstruation and Impregnation.—Dr. L. Remfrey, in a paper read before the Obstetrical Society, London, concludes as follows: 1. Of nursing women, fifty-seven per cent. only have absolute amenorrhœa. 2. Forty-three per cent. menstruate more or less, but twenty per cent. have absolute regularity. 3. Impregnation does not take place so readily during lactation as at other times, but this is not true to such an extent as has been imagined. 4. If absolute amenorrhœa is present during lactation, the chances of impregnation occurring are only six out of one hundred. 5. If menstruation occurs during lactation, the chances are sixty in one hundred. 6. The more regular a woman is during lactation the more likely is she to become pregnant. 7. During a menstruating lactation the changes in the uterus are presumably similar to those connected with the ordinary monthly periods, and the mucous membrane forms a nidus for the ovum. 8. In the woman who does not suckle at all, the menses appear, as a rule, some time in the first six weeks after delivery.

Acute Gout.—Dr. Jaccoud (*La Semaine Médicale*) divides this subject into three parts, according as one has to deal with the acute attack proper, the subacute attack, or the recurrent disease. In the acute attack proper he does nothing during the first five days except to promote diuresis by the most simple means, as the administration of a litre or so of Evian or Vittel water daily, perhaps adding a little acetate of potassium. He refrains from giving milk, as he prefers that the "explosive energy" of the disease be expended on the organic tissues themselves. He applies anodyne embrocations to the joints and covers with a thick coat of wadding. If at the end of five days the fever and pains have subsided, the attack is nearing its end and no further treatment is necessary. Now, milk should always be given. If there is no improvement, Dr. Jaccoud gives one and a half grains of hydrobromate of quinine with three-quarters of a grain of digitalis powder in pill form five or six times a day: this nearly always produces the desired effect in two days. If the pains are worse at the fifth day than at the onset, salicylate of sodium in thirty to forty grain doses should be given if the urine is free from albumin; after the second dose the urine is to be tested with ferric chloride, and, if the salicylate reaction is either feeble or wanting, the drug should be stopped. The subacute form of the disease is characterized mainly by its prolonged duration. If the above treatment does not cut short the attack on the ninth or tenth day, we must resort to colchicum. The author gives this in the form of pills. He uses Becquerel's formula, each pill containing one-half grain of extract of digitalis, two grains of sulphate, or, better, hydrobromate of quinine, and one-half grain of colchicum seed. In order to avoid excessive purgation, not more than two pills should be given a day. No special antigout medication is to be employed between the attacks. Recurrent gout is treated in about the same way as the subacute form. Visceral gout unassociated with articular symptoms is a late complication, coming on only after years of typical gout. If there is no joint affection within twenty-four hours, colchicum is to be given at once. The joints usually affected are to be covered with powerful revulsants and vigorously blistered.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 19, 1896.

THE PARALYSES OF TOXIC ORIGIN.

THE so-called toxic paralyzes are characterized especially by their peripheral localization and symmetry of distribution. They involve particularly the extensor muscles and exceptionally also the optic, phrenic, and pneumogastric nerves. The affected muscles undergo atrophy and lose their contractility, while the invaded members become fixed in partial flexion from unopposed action of the unparalyzed muscles. The paralysis extends, as a rule, from below upward, and may be designated "ascending." The motor manifestations are usually preceded by subjective disturbances of general sensibility, such as pricking, numbness, tingling, symmetrical in distribution and localized especially in the extremities of the members. In addition, there are objective disturbances of general sensibility, of similar distribution, with almost constant integrity of special sensibility. Finally, there occur vasomotor and trophic disturbances, also symmetrical in distribution, and, as a rule, of maximum severity in the lower extremities, though occasionally found in the upper.

Among the intoxications in connection with which the paralyzes under consideration have been observed are those due to lead, arsenic, mercury, alcohol, and the infectious diseases generally. The source and origin of these intoxications are sometimes so obscure and the symptoms to which they give rise occasionally so anomalous, that one must constantly be on his guard lest he go astray in diagnosis and, as a result, fail in his treatment. So like the symptoms of posterior spinal sclerosis are the manifestations of some of these cases, that they have been injudiciously designated "pseudo-tabes."

It has been observed by Lancereaux¹ that arsenical paralysis may be attended with febrile symptoms, thus simulating typhoid fever or acute miliary tuberculosis, or other continued fever, and he reports two illustrative cases. A girl, thirteen years old, previously in good health, was seized with vomiting, vague pains, a sense of fatigue and backache, to which soon was added elevation of temperature, at times reaching as high as 104° F. The pulse was accelerated, but there was no headache and sleep was fairly good, and there was no evidence of organic disease. The symptoms thus continued for four or five weeks, when numbness at

the tips of the fingers and toes was complained of. Next the feet became painful and movement difficult. The nutrition, which had hitherto been maintained, now began to fail and the patient was disturbed by dreams. The skin became dry and rough, and the complexion assumed a leaden aspect. The legs were partially flexed upon the thighs and the toes upon the feet, from weakness and wasting of the extensor muscles. At this time, more than three months after the beginning of the illness, the possibility of a toxic paralysis suggested itself, and on inquiry it was learned that the patient had been under treatment with arsenic for three years, for the relief of a generalized psoriasis. Under appropriate treatment, especially of a symptomatic character, improvement at once set in and progressed favorably.

In the second case, which occurred in a woman thirty-eight years old, who had been taking daily for ten months from ten to fifteen drops of Fowler's solution for the dissipation of enlarged cervical and axillary lymphatic glands, it was decided without a knowledge of this fact to prescribe the same medicament, in doses of from ten to thirty drops in the twenty-four hours. In the course of three weeks fever manifested itself, with vomiting and looseness of the bowels. There was also complaint of dryness of the throat and of the inner surface of the cheeks, with difficulty in mastication; also of headache, with a sense of constriction about the forehead; and, finally, of numbness, tingling, prickling, and burning in the fingers, especially at night. Later there was actual impairment of sensibility and of motility as well, with abolition of the reflexes and œdema of the lower extremities, followed by desquamation. Upon the withdrawal of the medicament the temperature declined, although the pulse remained accelerated. When the drug was resumed, however, the previous symptoms also were renewed.

These two observations not only confirm the knowledge that small doses of arsenic taken for long periods are capable of exerting a toxic influence upon the nervous system rather than upon the gastro-intestinal apparatus, but they also show that they may give rise to febrile symptoms whose origin is likely to escape detection unless the clinician be on the alert. They further enjoin especial care in the administration of arsenic for therapeutic purposes. It remains to be seen if similar manifestations attend other forms of toxic paralysis.

THE COURSE OF TYPHOID FEVER.

IN comparison with some cases of typhoid fever, few other diseases cause the physician greater hesitancy in diagnosis or greater anxiety as to final outcome. When the nature of the affection is not perfectly clear, he hesitates to say that the case is not one of typhoid fever for reasons some of which urge him as strongly to withhold that diagnosis—long days of vigilance, search for the source of infection, disinfection and disposal of passages, and protracted dietary and course of treatment, etc. In a study of the evolution of typhoid fever by Bernheim, of France, some light is

¹ Bulletin de l'Académie de Médecine, 1896, No. 28, p. 41.

thrown on the cause of the irregular course and varying symptom complex of this disease.

Bernheim says that the so-called normal type of typhoid, such as described by Wunderlich (period of augmentation of three to four days; stationary period, twelfth to fourteenth day; and period of decline, five to six days), is not the most common. While this may be retained as a schema, alongside of it should be mentioned typhoid with shortening of the stationary period, or abortive typhoid; and typhoid with prolongation of the stationary period, or prolonged typhoid. In the first the microbic evolution is aborted and the lesions in Peyer's patches resolve without ulceration. In the second the microbic evolution is not continuous, but occurs by steps. Pathological anatomy shows that the lesions are not all contemporaneous, some being in a state of ulceration or cicatrization, while others are in the stage of hyperplasia.

According to whether the first microbic evolution is only in a state of regression or whether convalescence has actually begun when a second evolution sets in, would he call it a recrudescence or a relapse. In both instances, however, the cause is the same—successive evolutions of the typhoid germs. He found relapses in one-fourth of the cases, and, adding together the cases with recrudescence and those with relapse, the number amounted to one-third of the whole. The recurrences may be abortive, but at other times they are long continued and grave. The persistence of the typhoid bacillus in the economy for several months after convalescence, as shown by Orloff, Dupré, and others, goes to confirm this view, based on the clinical history. The relapses may cause no other symptoms than rise of temperature, which may continue for weeks or for only a few days. An irregular fever may follow and be due to secondary infection from staphylococci or attenuated streptococci. Hemorrhages, pneumonia, myocarditis, etc., may alter the regular course of typhoid.

While this theory of the development of typhoid fever by successive stages of microbic infection, giving rise to a varying clinical picture and influencing the prognosis, may be new to the general profession, yet we presume that Bernheim would not disclaim the possibility of its having occurred to others during the twenty years that he has himself entertained it, especially since it might be suggested by what seems to be a more or less analogous condition seen in pneumonia, diphtheria, and perhaps other infectious diseases.

THE COMMISSIONERS OF PUBLIC CHARITIES AND THE PUBLIC HOSPITALS.

WITH the return of physicians to town and the advent of autumn, the vexed question which, during the past winter, has troubled the medical profession with regard to the appointment of physicians to the various medical positions in the gift of the commissioners will come up again for consideration, for the matter is by no means settled, nor can it ever be settled to the satisfaction of the medical profession of this city until its rights are fully recognized both by the commissioners and by the medical colleges.

The question underlying this subject is not with re-

gard to the reappointment of the men who lost their positions, for it is fully recognized that the commissioners had the undoubted right to declare their positions vacant if they saw fit; but that the right of nomination, and it may almost be said that of appointment, should rest with the colleges, to the debarment of the general profession, unless the candidates have the stamp of the colleges, is a matter of such gross injustice that until this wrong is righted no rest will come to either the commissioners, the medical profession, or the colleges. But were the right of nomination taken away from the colleges, upon any vacancy occurring the commissioners would at once be besieged by requests from medical men for appointment, and their lives would be made more or less of a burden in trying to adjudicate this question upon equitable grounds. To the non-political mind it seems extraordinary that the commissioners should voluntarily place this burden upon their backs, when it can so easily be gotten rid of with comfort to themselves, benefit to the hospitals in their care, and advantage to the public as well as to the medical profession. If the commissioners should make the service a continuous one, appointing one man to each division of the hospitals, and make the positions salaried ones, the method of appointment would be much simplified; for the moment these positions are made salaried ones, they come under the action of the civil-service law, and the commissioners could at once refer all applicants to the civil service examining board, which would pass upon their capacity and fitness to hold the positions to which they desired to be appointed. Nor is this an impossibility or without precedent. The New York Dispensary, after trying the old plan of appointment, has now made its medical and surgical positions salaried ones, with advantage both to the men holding the positions and to the dispensary under their control. The same is believed to be true also of the Good Samaritan Dispensary (the old Eastern Dispensary); and in order to supply funds for the payment of its medical officers—for the medical laborer is worthy of his hire—the schools should be required to pay a stated sum for each student who enjoys the hospital facilities furnished by the city. At the McGill University of Montreal, we understand, the students are charged for a hospital ticket, and there is no reason why the medical schools here should not be required to pay for these advantages to their students. This would at once raise the position held to one of dignity and honor to the profession, and prevent the unseemly scramble and intrigue which goes on to obtain hospital appointments in the municipal service. It is difficult to see what reasonable objection there could be to this plan, and certainly, so far as the commissioners themselves are concerned, it would free them from this annoying feature of their labors and give them more time for the study of the duties with which they are entrusted and the proper study of which would fully occupy their time.

"All Kinds of Hot and Cold X-Rays now on Exhibition" is the mysterious legend over a booth at one of the popular seashore resorts near this city.

News of the Week.

The Hack Tuke Memorial.—It has been suggested that the memory of the late Dr. D. Hack Tuke should be perpetuated in connection with the work to which he devoted his life, viz., the amelioration of the condition of the insane and the advancement of neurological and psychological medicine. With the view of carrying out this object, a committee has been appointed to solicit subscriptions in the United States and Canada. The fund obtained will probably be used to found a library in connection with the British Medico-Psychological Association, to which Dr. Tuke's personal library has already been given. Subscriptions may be sent to Dr. Charles W. Pilgrim, Poughkeepsie, N. Y.; Dr. Charles G. Hill, 317 North Charles Street, Baltimore, Md.; or Dr. Frank C. Hoyt, Clarinda, Ia.

The Death Rate in New York during the hot week ending August 15th, was 48.65. The number of deaths was 1,810, of which 615 were from heatstroke.

A Ladies' Quarrel.—The life of a British army surgeon is not a pleasant one. The commander-in-chief of the army treats the members of the medical corps as menials and snubs them at every opportunity; and now it is said that their wives are treated as inferiors by the wives of the combatants, and unhappiness reigns.

The Dirty Sponge.—Professor Lang, of Vienna, declares that sponges, owing to the impossibility of destroying germs in them, have long since been banished from the surgeon's table, and should also be excluded from the bathroom and washstand.

Sewage Farms.—In Paris one-fifth of the sewage is utilized for sewage-farm purposes. For some twenty years the municipality at Gennevilliers, outside Paris, has had several hundreds of acres (once waste land) irrigated, and they now bear magnificent crops of roots and kitchen-garden products. The sewage, after percolating the soil, exudes as pure water. The municipal council, after local opposition, acquired two thousand acres of a Sahara-sandy lightness in the forest of Saint Germain. For two years this district has been irrigated with sewage, and is now covered with luxuriant agricultural and gardening crops.—*Medical Press*.

Suggestion in the Prevention of Seasickness.—Dr. Gorodichze recently reported to the Paris Society for Hypnology that he had succeeded, by means of hypnotic suggestion, in preventing seasickness, even in the case of persons who had always been violently affected by it.

Theses de Paris.—A proposal was recently made, and we believe considered by the authorities of the Paris Faculty, that the thesis which forms the final act in the process of examinational evolution of the doctor of medicine should be abolished. Whether this ancient institution is seriously threatened we cannot say, but there is certainly no sign of its immediate

suppression. During July no fewer than two hundred and thirty-six theses were presented, making a total for the past academic year of five hundred and ninety-four. This is the largest number ever presented in one year. The total number presented since 1798, from which the faculty in its present form dates its existence, up to the end of July, 1896, is thirty thousand nine hundred and fifteen.—*British Medical Journal*.

Dr. John B. Hamilton, the able editor of the *Journal of the American Medical Association*, and also surgeon in the Marine Hospital Service, has been ordered, in the latter capacity, to leave Chicago and proceed to the station at San Francisco. The association can ill afford to lose Dr. Hamilton's services, for he has done much to make the *Journal* what it is, and we trust a way may be found to reconcile his present conflicting duties. The *Journal*, under Dr. Hamilton's editorial management, has been an active opponent of the project to entrust to the Marine Hospital Service the duties of the proposed department of public health.

Match-Making by Machinery.—The French government has been endeavoring to prevent the use of white phosphorus in the making of matches, but finds that to forbid it would be practically the same as prohibiting the making of matches. It has, therefore, sent an engineer to this country to report upon the machines used here for making matches, with a view to their adoption in the French factories, so as to do away with the making of matches by hand.

The Jenner Centenary in Russia will be celebrated in St. Petersburg, on October 24th. The Russian correspondent of the *British Medical Journal* says that the preparations of the Russian National Health Society for this commemoration are proceeding apace. The centenary edition of the society's publication, containing a life of Jenner and translations of all his works, as well as a historical notice of the development of vaccination in Russia and other European countries, will be a worthy memorial of the occasion. It will contain considerably over a hundred illustrations, many of them most admirable reproductions of Jenner's original drawings; it will also contain portraits of Jenner, views of the Berkeley neighborhood, and a host of other Jenneriana, which should make the volume one well worth possessing, notwithstanding that the letterpress will be in Russian. The subscription for the edition is the small one of 3 roubles, or rather over 6s., which will probably be less than the cost of production. Already the society has received a large number of loans and gifts for the exhibition, which it is proposed to hold in connection with the commemoration. These objects have come from almost every part of the world; there are contributors from such distant countries as Japan, the Cape of Good Hope, the East Indies, and Brazil.

Port Physician of Wilmington, Del.—Dr. M. J. Hughes has been appointed by Governor Watson port physician of Wilmington, in succession to Dr. Willard Springer, resigned. The port physician is also *ex-officio* a member of the city board of health.

Vital Statistics of Philadelphia.—For the week ending September 5th there were reported in the city of Philadelphia 362 deaths, as compared with 356 for the preceding week and 355 for the corresponding period of last year. The deaths were distributed among 200 adults and 162 minors; 196 males and 170 females. Ninety-six occurred in children under one year of age; 38 in adults between sixty and seventy; 36 between fifty and sixty; 35 between thirty and forty; 30 between twenty and thirty; 25 in children between one and two; 23 in adults between forty and fifty; 22 between seventy and eighty. The most conspicuous causes of death were: Pulmonary tuberculosis, 44; marasmus, 33; cholera infantum, 22; senility, 19.

Pathological Society of Philadelphia.—At the stated meeting of the Pathological Society of Philadelphia, on September 10th, Dr. C. W. Burr exhibited a diffuse meningeal tumor from the left frontal region, probably a round-cell sarcoma, in association with syringomyelia, in a case of chronic nephritis presenting during life right hemiplegia and immediately before death general convulsions followed by coma. Dr. J. Dutton Steele presented tuberculous suprarenal glands from a case exhibiting also tuberculosis of the lungs, intestines, and mesenteric glands, but free from obtrusive symptoms of Addison's disease. Dr. Joseph McFarland presented a specimen of extensive neoplastic involvement of the abdominal cavity, matting together stomach, transverse colon, spleen, liver, and omentum above, and the uterus and the pelvic contents below. The interior of the stomach was free. The growth was believed to be an endothelioma, but the point of origin remained obscure. Dr. A. E. Taylor made some remarks on the epithelium and the lymphatic tissues of the foetal vermiform appendix, and exhibited sections stained by differential methods. Dr. H. W. Cattell presented a fresh specimen of aneurism of the arch of the aorta without rupture, and also one of multiple sacculi of the bladder.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States Navy for the week ending September 12, 1896: September 10th.—Passed Assistant Surgeon C. F. Stokes, orders of July 21st modified, detached from duty as member of the naval and medical examining boards, New York, and ordered to continue as recorder.

Philadelphia County Medical Society.—At the stated meeting of the Philadelphia County Medical Society, held on September 9th, Dr. G. Betton Massey read a paper entitled "Electricity in Gynecology at the Howard Hospital; Report of Cases." One hundred and two cases treated by these means were analyzed, the results reported being in the majority of a most favorable character. The largest number were cases of fibroid tumor of the uterus. Dr. John Lindsay made a "Report of a Case of Prostatic Abscess," which presented symptoms resembling those of influenza and terminated by spontaneous rupture into the urethra. The condition was recognized by the detection

through the rectum of enlargement of the prostate gland. Dr. J. B. Roberts referred to a similar case, in which rupture took place through the urethra and through the rectum as well; an abscess also formed in the scrotum.

Obituary Notes.—DR. ALEXANDER H. MCADAM, a well-known and successful practitioner, died at Philadelphia, on September 9th, in his fifty-seventh year. He was graduated from the University of Pennsylvania in 1863, and he was for a number of years a member of the select council. At the time of his death he was a member of the board of education.—DR. EDOUARD NICAISE, of Paris, died of pneumonia in that city, in the latter part of August. He was born in 1838, and was graduated in medicine in 1866. He was surgeon to the Hôpital Laënnec, and for a number of years was editor of the *Revue de Chirurgie*.—DR. WILLIAM T. TURNER died at Philadelphia on September 9th, at the age of twenty-two years. He was graduated from the University of Pennsylvania in 1895.—DR. WILLIAM CRANCH BOND FIFIELD died at his home in Boston, Mass., on September 9th, aged seventy-eight. He was a graduate of Harvard Medical School in 1851, and of the Royal College of Surgeons in England.—DR. NICHOLAS RUDINGER, professor of anatomy at Munich University, died on August 24th, at Tutzing, in Bavaria. He was born in 1832, at Büdesheim, in Hesse. After studying medicine at Heidelberg and Giessen, he was appointed prosecutor at the anatomical institute at Munich in 1855, and in 1880 was made professor of anatomy at the university.—DR. HENRY K. PUSEV died at Garnettsville, Ky., on September 2d, at the age of seventy years. He was graduated from the medical department of the University of Louisville in 1849. He was for a number of years superintendent of the Lakeland Insane Asylum.—DR. HARRY HODGEN, of St. Louis, died at Alma, Mich., on August 28th. He was a son of the late Dr. John T. Hodgen, and was born in 1855. He was graduated from the St. Louis Medical College in 1883, and was professor of orthopedic surgery in the same institution at the time of his death.—DR. JOHN LOUIS HOPKINS, of New York, died August 21st, from heart disease. He was born at Carthage, N. Y., in 1861, was educated in the Carthage Academy, and was graduated in medicine from the New York University in 1887. He soon acquired a remunerative practice, and, like many physicians, he was himself the last to receive his consideration. So far, indeed, had he carried this self-abnegation, that his fatal illness seized him while in the midst of his work and he died two days after taking to bed.

An Association of Nurses.—A number of nurses, representing training-schools and alumnae associations, met at Manhattan Beach Hotel, on September 2d, to organize an association of nurses which shall cover the United States and Canada. A constitution was drafted, which will be submitted for ratification to the different bodies represented. The object of the proposed association is to bring the nurses of the country into closer union, to protect them in their rights, and to elevate the profession of nursing.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF VIRGINIA.

Twenty-Seventh Annual Session, Held at Rockbridge Alum Springs, September 8, 9, and 10, 1896.

(Special Report for the MEDICAL RECORD).

First Day—Tuesday, September 8th.

THE meeting was called to order at 8 P.M. After a prayer and the report of the committee on applicants for fellowship, MR. ALEXANDER H. GRAHAM, of Austin, Tex., delivered an address of welcome to the assembled doctors.

Moderation an Aim in Education was the subject of the address to the public and profession by DR. ELLIOTT E. BRADY, of Chatham Hill, Va. In this he claimed that moderation is a natural law, and that the violation of the law brings with it appropriate penalties. He denied the theory of the inheritance of evil propensities, and advocated the early education of children, beginning in absolute infancy. He claimed that at the age of five years, the time usually chosen for beginning educational methods, the tempers and temperaments of children were almost unalterably formed. He called attention to the fact that the theory of non-accountability of criminals and drunkards, on the ground of hereditary tendency, has a tendency to affect injuriously our criminal laws. He styled the theory as the greatest social and moral error of the century, saying, in the course of his remarks, that "the theory invented by experts in excess to shield a criminal behind the mythical scapegoat of parentage, has saved many a neck which laws inaugurated by common sense had prepared ropes to stretch."

Second Day—Wednesday, September 9th.

The Progress of Medicine in Relation to the Prevention of Infectious Diseases.—DR. W. L. ROBINSON, of Danville, the president-elect, delivered an address with this title. The points discussed were the evidence of the bacterial origin of disease and the prophylactic value of orrhoterapy; the special modes of infection of typhoid fever and tuberculosis and the means to be employed in stamping out these diseases; the establishment of a department of public health of the central government, the chief of which should be a member of the President's cabinet.

Intestinal Indigestion.—DR. L. G. PEDIGO, of Crockett Springs, Shawsville, opened the discussion on this subject with a paper on the treatment of this condition. He said that the subject illustrates most forcibly the notion of the interdependence of the various organs. It teaches us how impracticable it is to divide up the various organs and assign them to the corresponding specialists for treatment, as a mere machine might be repaired. He set forth the indications of treatment as follows: (1) To see that gastric digestion is as nearly normal as possible; (2) to attend to the removal of all obstruction from the colon; (3) to endeavor to restore muscular tone to the entire alimentary canal and to promote regular peristalsis; (4) to obtain a careful regulation of the liver in all its functions; (5) to see to it that the pancreatic and salivary secretions are normal in quality and quantity; (6) to promote intestinal antisepsis, or the prevention of the abnormal fermentation; (7) to do all possible to favor certain of those forms of so-called "fermentation" (diastasic action) on which intestinal digestion depends; (8) to prevent the absorption of the toxins from the intestines; (9) to secure the elimination of these

toxins through various channels, chiefly the kidneys; (10) to prevent and remedy the depressant and destructive effects of the toxins upon the nerve centres; and (11) in the after-treatment to build up the blood, which has been impoverished. These indications, the speaker said, are to be met by physical, dietetic, hygienic, and medicinal measures. Antisepsis was approved, but the difficulties in the way of its accomplishment were pointed out, and the reasons shown why it was disappointing in its effects when employed without due preparation of the patient. Great stress was laid upon flushing the colon, washing out the stomach, regulating the functions of the liver, a careful line of diet, and systematic exercise "from the hips up." Among special intestinal antiseptics, subgallate of bismuth was highly spoken of, the practice of the author being to combine it with large doses of subnitrate of bismuth. Salol was also praised for selected cases, and beta-naphthol-bismuth was favorably mentioned. Of diastasic agents, a well-prepared pancreatin should be used.

DR. UPSHUR, of Richmond, called attention to the necessity of a more careful analysis of cases and a consideration of the underlying physiological principles. He divided the cases into functional and organic, and discussed the various causes, whether located in the intestine, stomach, liver, pancreas, or kidney, or nervous in character. He called attention to the trouble in children from mental strain at school. The effect of taking more food than the system requires, dress, and habitual faulty positions of the body were considered, and a correction of these causative conditions was urged as essential. Dr. Upshur also called attention to the ill-effect of tobacco in its physiological action on the salivary glands and pancreas. He reviewed the symptoms fully from every standpoint, calling attention to the significant fact of pain in the right hypochondrium coming on, in the chronic form, from one to three hours after eating. The neurasthenic symptoms were also discussed. The prognosis, he said, depends upon the acuteness of the case and the nature of the complications, functional or organic.

DR. JACOB MICHAUX, of Richmond, expressed surprise at the general misconception as to the cause and management of the disease. He believed in the employment of muscular exercise, but did not believe walking sufficient, and urged his patients to employ all the exercise possible in the open air. A very successful remedy in his hands had been a brine sponge bath upon rising in the morning. Tepid water was employed in cold weather. He also was in the habit of rubbing a saturated solution of salt into the skin. In the form of chronic diarrhoea he gave his patients milk, either alone or with lime water or salt. When they could not stand milk, he gave animal broths. He adhered strictly to a liquid diet. As regards drugs, he had found the digestive ferments of the greatest service. Tonics were rather hurtful. Iron would do more harm than good until substantial food could be digested. Quinine had been shown to be an irritant in most cases. He had been in the habit of relying largely upon pepsin and lactic and hydrochloric acids after meals, or a solution of the chloride of arsenic in minute doses. In some cases he gave from twenty to sixty grains of bismuth, with five grains of salicin, two hours before meals: and two hours after meals he used the extract of opium. Active medicines he regarded as dangerous. He had found the keynote of success to consist in strict attention to diet.

DR. I. S. STONE, of Washington, D. C., said that he did not regard such fine distinctions between cases of intestinal indigestion as at all essential. While he most heartily approved the views of the gentlemen who had spoken, he thought a more practical method of diagnosis and treatment could be devised and prac-

tised. Intestinal indigestion was due to either functional or organic disease. The organic cases were not necessarily difficult to treat. The functional were often due to nervous causes. Treatment addressed to the general condition of the patient would cure, while remedies generally given for dyspepsia would fail. Lavage, used before breakfast, or the use of a pint of hot water sipped slowly, would wash out the collection of mucus sometimes found in the stomach. Hydrochloric acid, in addition to this, would also prove useful. Massage, proper exercise, and a suitable environment were often necessary, and without these the usual remedies, especially the so-called digestive ferments, were useless.

DR. W. S. GORDON, of Richmond, thought that most cases of biliousness begin in the stomach. He laid great stress upon the influence of the nervous system in intestinal disturbance. Functional diseases of the alimentary tract do not show post mortem. Gas in the stomach is not always due to intestinal indigestion. He had seen cases of periodic flatulence well marked in children, which he was sure were due to a nervous condition of the stomach. He had found asafœtida a most invaluable remedy in such cases. Hysterical women often suffer greatly from flatulence, which he was convinced was due to exosmosis of gas from the blood into the intestinal canal.

The presence of oxalate of lime in the urine does not possess much diagnostic value. When it develops in the duodenum it is always present in the urine. He had relieved this condition temporarily by the use of muriatic acid. He gave mercury for its sialogogue action on the pancreas. Pancreatin does not act with much power upon the stomach.

DR. R. M. SLAUGHTER, of Theological Seminary, Fairfax County, had obtained the most uniform benefit from the employment of the stomach pump. He also used copious enemata with a two-foot colon tube. He thought the pancreatic solvents did good. Vegetable pepsin had cured a case of ten years' standing. For washing out the stomach he used plain boiled water. He used the stomach tube three or four hours after meals, but gave enemata only once a day.

DR. UPSHUR thought that Dr. Stone was right as far as he went, but did not go far enough. The condition begins in the stomach and reflex action is from there set up. A hard-worked doctor who suffers from intestinal dyspepsia wants rest and not exercise. Very often a faulty condition of the kidneys forces the stomach to act vicariously as an excretory organ. He used nitroglycerin to relieve vascular tension and so enable the kidneys to resume their proper function. He was opposed to the employment of intestinal ferments. He sometimes used pepsin as a base mixed with phosphoric acid or strychnine. When any digestive was indicated, he used pancreatin pure and simple. He was opposed to the indiscriminate employment of medical preparations of unknown composition.

DR. PEDIGO said that exercise, to be useful, must be of the proper kind. He did not regard anæmia in these cases as due to lack of nourishment, but to the presence of toxins in the intestinal canal. It is the function of the kidneys to eliminate this poison from the blood. This toxic wave of elimination is always passing through the system. If it stops, sickness or death supervenes. In cases of suggestive intestinal indigestion the nervous condition is due to the action of these poisons on the nervous system and so to reflex symptoms. The speaker was very cautious in the administration of tonics. He thought that Dr. Michaux's suggestion of brine baths was excellent. He usually regarded diarrhœa in intestinal indigestion as incidental and did not combat it actively. He had excellent results with hot-water injections in this diarrhœa.

Cold enemata following the hot were also useful when it was necessary to check it. He used quinine only in cases in which he suspected a malarial element.

Typho-Malarial Fever.—DR. WILLIAM S. GORDON, of Richmond, read a paper on the nature of this fever, taking the ground that there was doubt as to the existence of such a disease. He claimed that it is a typical typhoid and adduced arguments to prove his position from a clinical standpoint. He denied that the existence of a new disease with a specific germ has been proven. He also denied the existence of a hybrid disease, and was inclined to regard it as doubtful whether two specific fever germs could be present and active at the same time in the same body and produce a modified disease. The history of these cases proves that they cannot be distinguished in many instances from a group of cases resulting from typhoid poison, and the speaker held that it is more reasonable to prove them typical typhoid than to assume them typho-malarial. He would not absolutely deny that there is such a disease as typho-malarial fever until the point has been settled by bacteriological investigation. He denied the existence of catarrhal and gastric fever as distinct diseases. The history of malarial fevers as ordinarily described, especially from the standpoint of epidemics, shows them to be of typhoid nature. From the patient's standpoint, therefore, it is far better to suspect and treat the case as one of typical typhoid fever than to let the patient walk about in a disease supposed to be of small moment. The paper presented the question from both an argumentative and a clinical standpoint. It was discussed by a number of the members, but no new arguments bearing upon the existence or non-existence of such a condition as that under discussion were brought forward.

Hysterectomy.—DR. I. S. STONE, of Washington, D. C., read a short paper on "Extirpation of the Uterus for Pelvic Suppurative Disease." The author gave his reasons for abandoning the vaginal operation save in exceptional instances. He was struck with the admirable reports of Jacobs and others, and had made an effort to apply the new or vaginal method in his practice, but he had returned to the abdominal method, by which he had obtained most satisfactory results. A brief allusion was made to the technique of the method employed in order to show its reasonable superiority over the former method. The pus sac is removed if possible without rupture. The peritoneum is not soiled. The cornua of the uterus are excised and if necessary all of the uterus is removed. The uterus, if it is to be left in the pelvis, may be sutured to the abdominal wall. No ligatures *en masse* are used, the vessels being tied with small silk, a needle being used which permits fixation of ligatures, preventing any possibility of slipping.

The wound is not infected, the scar remaining is a mere pin scratch, and the patient does not think much about its presence. The vaginal method will never be adopted by any one having perfect results from the abdominal operation. The surgeon's imperfect work may be to some extent hidden from view when the vaginal method is selected, and it is possible that in some cases the mutilation is excessive and unnecessary, as the sacrifice of the uterus is absolutely guaranteed from the start. It is obviously true that when the abdominal method is chosen, the uterus may possibly be left and the appendages on one side at least. Many cases could be cited in which pregnancy followed the removal of the adnexa of one side only for pyosalpingitis.

DR. GEORGE TUCKER HARRISON, of New York, thought it was all important in young women to spare the ovaries. He objected to the suprapubic method because by the vaginal route conservation was practised

and no wound of the abdominal cavity was made. There is always danger from hemorrhage by the abdominal route. The tendency of modern surgeons is to take the vaginal route.

DR. GEORGE BENJAMIN JOHNSTON, of Richmond, thought it was difficult to operate in this way when the vagina was small and the perineum rigid. He preferred the suprapubic route. The operation can thus be done without rupture of tubes. There is also no special danger of infection.

DR. J. MCFADDEN GASTON, of Atlanta, thought the tendency of modern gynecology was to go through the abdomen. It is especially unnecessary to extirpate the uterus. He urged conservatism.

DR. WILLIAM L. ROBINSON, of Danville, said we could not see so well in the vaginal operation. There are adhesions and suppuration in most cases. The cleaner and better mode is by abdomen, as these adhesions have to be removed.

DR. STONE thought that he and Dr. Harrison were considering a different class of cases. The vaginal operation will not do when the case is severe. The vaginal way is a good one for preliminary investigation.

Third Day—Thursday, September 10th.

DR. R. J. PRESTON, superintendent of the State Asylum for the Insane at Marion, Va., offered a resolution that a commission be appointed to consider the recommendations and suggestions contained in the president's address, especially in reference to State and national hygiene, and that said commission recommend such action as it might think advisable.

Election of President.—DR. GEORGE BENJAMIN JOHNSON, of Richmond, was elected *President*.

Surgical Immunization.—DR. J. MCFADDEN GASTON, of Atlanta, read a paper on "Surgical Immunization Compared with Susceptibility and Predisposition to Infection," in which he reached the following conclusions:

"1. Various agencies are at work in rendering the human organism to a greater or less extent free from the injurious impressions of surgical procedures.

"2. Local and constitutional influences operate in conferring immunity, and the environments of individuals, with their habits and customs of life, exert great control over the vital powers.

"3. Certain marked changes in the conditions of the nervous system, constituting shock, in course of surgical operations, may be averted by proper measures in advance; and in default of such precautions should be corrected by rigorous means of treatment.

"4. The immunity for normal structures in operative work, which was supposed to be given by germicidal solutions, has proved to be a delusion and a snare, and that they are only admissible in septic contamination of the tissues.

"5. That a preliminary examination of all the functions of vital organs should precede surgical operations of every kind, and that efficient correctives should be resorted to for their derangements. The issue of the case depends materially upon proper means of preparation for an operation.

"6. It is not essential for the management of a surgical case that the patient be placed in a hospital, but cleanliness in private quarters with proper nursing may secure entirely satisfactory results, by conforming to the ordinary surroundings of the patient.

"7. A thorough comprehension of the reciprocal relations of immunity and susceptibility should lead to the adoption of conservative measures in the practice of general surgery, and the use of the most radical and aggressive measures when indicated by the nature of the case.

"8. Those appliances which may promote surgical immunization should be adopted, and those measures which lessen susceptibility and predisposition to infection are warranted in all cases of surgical interference."

DR. EDWARD MAGUIRE, of Richmond, took strong grounds against the practical possibilities of asepsis. Patients brought in with crushed or mangled limbs cannot be treated aseptically. The germs are already in the wounds. The unbroken skin or mucous membrane is proof against the entrance of germs.

Oxygen in Anæsthesia.—DR. T. L. PEDIGO referred to the use of oxygen in ether or chloroform narcosis. The use of oxygen is frequently impracticable. Recently, efforts have been made to use oxygen continuously through the period of anæsthesia, with a view to preventing failure of respiration and heart's action. High professional authorities differ as to the measure of success. Some are pleased with the results; others equally eminent condemn the method because of the delay in the effect of the anæsthetic. He referred to the use of nitrite of amyl to revive a patient from ether or chloroform narcosis (originally suggested by the late Dr. Dabney, of Virginia). He spoke of having saved at least two lives by this treatment. This method has something in common with the use of oxygen, since it promotes oxygenation of the blood by stimulating the respiratory function. He referred in some detail to the effect of amyl nitrite on the blood, as observed in experiments of his own on the antagonism between amyl nitrite and prussic acid, made some years ago. He was now engaged on a series of additional laboratory experiments, the results of which he hoped to present to this society twelve months hence.

Treatment of Epilepsy, Medical and Surgical.—

DR. J. ALLISON HODGES, of Richmond, read a paper with this title. As there is no known anatomical basis of this disease, its treatment must be empirical. We should exclude all causes of organic disease, and treat the affection as a neurosis. It was most important to look to the diet and to proper exercise as adjuvants in the treatment. The speaker recommended a periodical change of treatment, and also an occasional change of location. He insisted upon the advantages of the sanatorium or colonization plan. He had given with benefit the bromides in small doses during the day, and trional at night. Other measures which he had found useful were Flechsig's opium-bromide treatment, nitroglycerin hypodermatically to abort attacks, and intestinal antiseptics and laxatives for putrefactive fermentations and autotoxæmias. Regarding surgical treatment, he reported nine patients operated upon, with two seemingly cured after eighteen months' interval; but he doubted the permanency of the results in these cases. For relief of reflex epilepsy, the remedying of defects in his experience served but to effect a temporary amelioration; yet he invariably removed the exciting causes if the disease appeared indubitably referable to them.

Chronic Diarrhœa.—DR. JACOB MICHAUX, of Richmond, read a paper on this subject. He briefly discussed the etiology, symptomatology, and pathology of the disease, and devoted considerable time to the treatment. The greatest importance was attached to the absolute enforcement of his rules as to diet. These were based upon the physiology of digestion. He insisted upon the exclusion of fatty and amylaceous articles of diet, the substances allowed being in every case liquid or semi-liquid and such as experience has shown to be most easy of digestion. To milk was given the first place. This could be taken without any addition or change, but if it were not well borne it should be boiled; this failing, a little salt might be added, just sufficient to impart an agreeably salt taste.

If these measures failed the milk might be predigested. Broths of beef or chicken should be used when milk was not tolerated. These, if made properly and not too poor (though without grease), he regarded as exceedingly valuable. Soft-boiled eggs and raw oysters or carefully stewed ones might be used. The speaker strongly deprecated the use of any but the mildest and most uniritating drugs, confining his drug treatment to pepsin and nitro-muriatic acid and lactic acid for the aid of gastric digestion and to malt extract for the intestinal. He gave bismuth subnitrate in full doses to control the diarrhœa, with five grains of salicin to each dose, say, three, four, five, or six times a day. In severe cases of long standing in which there is inflammation of the mucosæ, opium, lead, and camphor should be given as required, but he insisted that opiates be not used except for the purpose of moderating the diarrhœa and relieving pain.

Orrhotherapy of Tuberculosis.—DR. PAUL PAQUIN, of St. Louis, Mo., read a paper on this subject. His system of producing antitubercle serum consists of injections of tuberculin and tubercle toxalbumins in the horse daily for from three to six months and then using the serum of the horse's blood (thus rendered antagonistic to the germ of tuberculosis) by hypodermic or rectal injections in doses of from five to one hundred and twenty minims, daily or on alternate days. He reported two hundred and twenty-six cases of pulmonary consumption of various stages, among which not ten were in an early stage. The results were as follows: Recoveries (apparently complete), 40; improvement (to the point of the patient returning to his usual duties), 110; unimproved or remained stationary, 76.

DR. LANDON B. EDWARDS reported fourteen cases treated with serum. Two patients who were in the throes of death when treatment began died. Three of them, one an acute case (galloping consumption), recovered completely. Three are no longer declining and six are improved.

The society was then adjourned to meet next year at White Sulphur Springs.

THIRD FRENCH MEDICAL CONGRESS.

Held at Nancy, August 6-12, 1896.

The Application of Blood Serums in the Treatment of Diseases.—This was the first of the subjects for set discussion. DR. G. H. ROGER opened the discussion by giving an historical review of this subject. Héricourt and Richet first showed that a fatal dose of the staphylococcus for the rabbit could sometimes be offset by a subsequent injection of the blood of a dog, but the treatment failed three times in four. They then observed the important fact that all the rabbits recovered if the blood were taken from a dog which had itself previously been inoculated. In 1890 Bouchard made known that blood could be replaced by serum in the treatment of infectious diseases. Meanwhile, the bactericidal action of normal blood, and especially of the vaccinated subject, was studied. Behring and Kitasato demonstrated the highly important fact that the blood of animals vaccinated against the bacilli of diphtheria or of tetanus possessed the property of neutralizing the poisons produced by these microbes in proportions truly extraordinary. But it was to Roux, Martin, and Chaillou that honor was due for having rendered orrthotherapy practical.

It was necessary to choose an animal, such as the horse, capable of furnishing the serum in large quantity and free from toxic properties. The vaccination could be effected either by inoculation of living microbes, the injection of toxins obtained from artificial

cultures, or by injection of toxins taken from the sick. The first method would expose the patient to great danger. The second and third were employed according to the case. As to the organic liquids which could be utilized, serum had been used above all others, being injected under the skin. Milk was ten times less active.

Regarding the application of serum therapy, it could be said to have been tried in all known microbic diseases, and also in most of those in which the pathogenic agent had not yet been discovered, although supposed to be infectious: likewise in intoxication with venoms, alcohol, etc.

Taking up the infectious diseases of which the pathogenic agent was known, Selano and Marchoux had produced immunity from charbon or anthrax by sheep's serum, and it was expected to be applicable in the treatment of malignant pustule in man. Speaking of the serums against cholera, the most that he said by way of encouragement for this form of treatment was that it could be tried in man.

The serum of rabbits vaccinated against the pneumococcus had been tried by various physicians in thirty-nine cases of pneumonia in man, with encouraging results. Roger thought meningitis of pneumococcic origin deserved a trial of this method.

Regarding the streptococcus, in 1895 Marmorek succeeded in preparing a serum by means of cultures of incredible virulence; a rabbit succumbed to a dose of one-ten-millionth part of a cubic centimetre. He easily immunized animals and obtained a most active antistreptococcus serum. Antistreptococcic serum was first applied to the treatment of erysipelas by Roger in 1895. Since then many trials had been made, but the results given had been so diverse that a definite opinion could not yet be formulated; still one could say that antistreptococcus serum was a useful adjuvant in the treatment of puerperal fever and grave erysipelas. The diverse results might depend upon mixed infection, and perhaps upon different varieties of the streptococci being unequally sensitive to the serum.

Experiments of all sorts had been made with regard to tuberculosis. The researches of Maragliano were very encouraging. The serum which he had prepared was bactericidal and antitoxic, curing tuberculous animals in the proportion of 16.26 per 100, and causing amelioration in 48.05 per 100. In man the serum rendered the tuberculous patient insusceptible to the action of large doses of tuberculin.

The treatment of variola with the serum produced by Béchère, Chambon, and Bénard, used in large doses, deserved trial. The serum therapy of several other diseases was mentioned, but that of diphtheria and tetanus was left for other authors. Among intoxicants, Phisalix and Contejean had shown that curare was deprived of its effects by the blood of the terrestrial salamander, which was almost insusceptible to this toxic agent.

In brief, vaccination by the serums possessed the advantage of vaccination by attenuation of microbes or their soluble products, in that its action was immediate. Being preventive, it could be used for prophylaxis, but the immunity which it produced was only passing.

Accidents of Orrhotherapy.—These were: abscess (from want of antiseptics), exanthems and passing arthropathies, fever, polyuria. The author thought nephritis could not be attributed to the serum, for it was not produced in experiments. Regarding death, it was possible that, like other therapeutic agents, serums might prove fatal under special conditions of susceptibility.

Speaking of the mode of action of the serums, the author thought serum-therapy was only a variety of an-

tidotal medication. When it concerned an antibacterial serum, there was introduced into the organism a specific antiseptic which influenced unfavorably the growth or function of the microbe. When it concerned an antitoxic serum, a substance was introduced which produced its effects upon the cells, augmenting their resistance or hindering their impregnation. Were we to believe that serum therapy was to become a panacea? Not at all. Diseased man was not comparable to an inoculated animal. A series of influences of diverse nature intervened in the evolution of the malady, the auto-intoxications, for example, and sometimes the employment of an artificial physiological serum might be indicated concurrently with a specific antitoxic serum.

The Application of the Serums to the Treatment of Diphtheria and Tetanus.—In a paper on this subject, DR. HAUSHALTER said the action of normal horse serum was only slightly toxic compared with other serums. But the injection of therapeutic doses of antitoxic serum in healthy rabbits was far from being innocuous, producing, according to Kossoroff, hyperæmia of the liver and kidneys, parenchymatous degeneration, etc.

Mode of action: All serums (normal, antitoxic, or artificial) possessed in virtue of their salts power to influence dialysis by modifying the constitution of the plasma; of acting dynamically upon the nervous system, favoring the development of local lesions; of fixing in part the bacterial secretions; of exciting and stimulating the phagocytes. Aside from these common properties, serums possessed toxic properties due to the albumins and ferments which they contained. The serums of the immunized also had germicidal and antitoxic properties, for the most part specific (Charin and Desgrez).

Mortality: Collective statistics showed that since the introduction of serum therapy there had been a general diminution of mortality in diphtheria, croup had become less frequent, recovery after tracheotomy and intubation had been much more frequent.

As to tetanus, the work of Roux and Vaillard had shown that serum could be preventive, but that it possessed no therapeutic property in cases of confirmed tetanus.

Mechanism of Immunity in the Rabbit against the Pneumococcus, and the Action of Antipneumococcic Serum of the Horse upon the Rabbit.—DR. DENYS, of Louvain, concluded from experiments on rabbits made in his laboratory by Mennes, that the immunity against the pneumococcus in rabbits was identical, in the action of the serum upon the leucocytes, with that observed in the same animal for the streptococcus, for the bacillus of diphtheria, and for the colon bacillus. In the course of four months, Mennes had produced a serum by hypervaccination of the horse which gave most excellent results when injected into rabbits experimented upon with the pneumococcus. The serum had a preventive and a curative action, and also the property of neutralizing the toxin produced by the pneumococcus. The opportunity had not yet presented itself for trying it upon man.

DR. RONDOT, in using Marmorek's serum for erysipelas, had observed rapid improvement of the general condition, with fall of the fever and diminution in the gravity and duration of the disease.

Immunizing Power of Normal Horse Serum against Diphtheria.—DR. FÉRE, of Bordeaux, had found that normal horse serum injected into guinea-pigs in some cases produced no immunizing effects against diphtheria, in others slight effects, and in others again marked effects. This would explain certain favorable results in the treatment of diphtheria in man with normal horse serum.

Contribution to the Experimental Study of Post-Orrhothropic Accidents.—DRS. BÉCLÈRE, CHAMBON,

and MÉNARD in some experiments injected the normal serum of the horse into heifers, with the result of producing fever and polymorphous eruptions simulating urticaria and rubeola, and even arthropathies—accidents similar to those frequently seen in man during serum therapy. On the other hand, heifers injected with serum of the same species and with that of the ass showed no such lesions. In the first-named experiments no microbe was found in the heifers to account for the symptoms, which it was concluded were of toxic origin. The authors concluded that the accidents attending the use of horse serum in man as well as in animals are not due to anything pertaining to the antitoxin, for which property it is administered, but to the serum itself, which serves as a vehicle.

A. TRELLE had not succeeded in some attempts at treating quartan ague with serum therapy—serum of Roux.

Significance of Phenomena Consecutive to Injections of Antidiphtheritic Serum.—BOSE, of Montpellier, in this paper considered the value or significance of fever, circulatory disturbances, and albuminuria, after injecting antidiphtheritic serum. These were normal reactions to the injection of sodium chloride and certain other agents in healthy animals, and in disease might, according to their characteristics, be beneficial. The same could be said of injection of antidiphtheritic serum—according to the characteristics of the reactions named might they be inferred to be beneficial or injurious in the case under treatment.

Serum Diagnosis of Typhoid Fever.—DR. F. WIDAL gave his further experience in the diagnosis of typhoid by the action of the serum of the individual (sick or convalescent) upon cultures of Eberth's bacillus. His study, pertaining to the serum of nearly a hundred persons, enabled him to affirm that the serum of typhoid patients, like that of patients convalescent from the disease, amassed the bacilli of Eberth suspended in bouillon, and agglutinated them in masses visible under the microscope. This action was so powerful that it could be observed in certain cases in which the mixture was in the proportion of one of the serum to sixty of the bouillon. The serum of persons never having had typhoid possessed no such agglutinating influence upon the bacilli of Eberth. Others had confirmed these observations. In actual study the proportion used should be one of serum to ten of bouillon culture, and the more recent the latter the better, although an older culture could be rejuvenated for the purpose. The agglutinative influence was manifest not only during convalescence, but also during the typhoidal attack. It was, therefore, of value in differential diagnosis. In twelve persons who had had typhoid fever from a year to nineteen years previously, it was manifest in only two, and of these one had had typhoid three years before, one seven years before. The phenomenon, therefore, seldom showed itself longer than a year after recovery. It could be relied upon in diagnosis by the sixth or seventh day of typhoid. The serum in producing the phenomenon did not sterilize the culture.

DR. VEDEL, of Montpellier, insisted upon similar agglutinating property for the serum of persons affected with coli-bacillary infections when introduced in cultures of Eberth bacilli.

Thyroid Medication.—DR. BOURNEVILLE gave recent results with thyroid medication. Four patients with myxedema, two of whom he had presented before, had continued to advance intellectually under the treatment, and the other two had increased in size, particularly in height. The oldest was fifteen years of age. The treatment had also been efficacious in four cases of obesity in patients under fifteen years and had caused slight growth in four cases of retarded develop-

ment in patients from eighteen to twenty-five years of age. For the most part he used the fresh gland, giving half a lobe every second or every day.

Pathogenesis of Intravascular Blood Coagulation.

—DR. MAYET read a paper in which he discussed the following conditions: 1, coagulation produced by vascular changes from causes outside the vein (contusions, etc.); 2, coagulations caused primarily by pathological changes within the vein (aneurism, etc.); 3, coagulations from modifications of the blood acting upon the nutrition of the walls of the vessels (chlorosis); 4, coagulation from blood changes aided by local circulatory trouble; 5, infectious coagulation (puerperal fever, etc.).

Pathogenesis of Intravenous Coagulation.—MAUREL in a paper on this subject drew certain conclusions, two of which were: (1) in most cases the thrombi were at their commencement leucocytic; (2) thrombi may be fibrinous or non-fibrinous, the former usually being of microbic origin.

DRS. SABRAZÈS and MONGOUR had found along the thrombic veins in phlegmasia alba dolens of cancerous and tuberculous patients chains of glands, which pointed to an infectious origin of the phlebitis. In some the tubercle bacillus was found.

DR. VIDAL then reported a case of slow obliteration of the right primary iliac vein, the process extending over years.

Infection and Symmetry: Pathogenesis of Bilateral Lesions.—DR. CHARRIN said that as to nephritis occurring during the course of infection, it was symmetry of function which caused symmetry of lesion. Certain viruses produced microbic infarctions on the right as well as on the left side, the calibre of the obliterated capillaries being previously diminished by paralysis of the vasodilators through action of the toxins upon the nervous centres. The action upon the centres—vasoconstrictor for the microbe of blue pus, vasodilator for others—was capable of modifying homologous areas, as in the members, and in those homologous areas symmetrical infection might take place through germs of the skin or those carried by the circulation. A lesion primarily local might secondarily become bilateral by analogous process. The influence of the nervous system was shown in paralysis, in which bilateral vaccination produced a greater lesion on the paralyzed side.

Difference in Virulence of the Tubercle Bacilli.

—DR. LOUIS DUBOIS said that grave general tuberculosis always corresponded to extremely virulent bacilli.

Orrhotherapy in Diphtheria at Marseilles.—DR.

D'ASTROS, between January 1, 1895, and July 1, 1896, had treated diphtheria in six hundred and sixty-eight cases out of one thousand and sixty-four bacteriological examinations, three hundred and ninety-nine not associated with other bacilli. The total mortality of cases treated with serum was 17.7 per cent.

Orrhotherapy in Variola.—DR. A. BÉCLÈRE had used the serum of the vaccinated heifer against variola in two infants, both of which recovered. A large quantity of serum, the twentieth part of the infant's weight, was introduced under the skin. Sometimes an eruption occurred six or ten days after the injection, but he regarded the treatment as inoffensive and rational. The serum of the heifer was better supported by the human organism than the serum of the horse.

DRS. BOUREAU and CHAUMIER reported some studies upon the microbes of vaccin, and SAINT YVES-MÉNARD stated that he had some very old vaccin which was at the disposition of the members, which had been shown to be sterile to culture, yet it retained perfectly its virulence.

Rheumatic Phlebitis with Autopsy.—DRS. VIDAL and SICARD reported the case, that of a woman, aged

twenty-eight, who had once before had polyarticular rheumatism. On the present occasion the rheumatism involved the four limbs, had lasted ten days, was improving under hospital treatment, when phlebitis developed in the arm. The heart became arrhythmic and death took place in asphyxia ten days after the occurrence of the œdema due to the phlebitis. The lesion localized in the axilla presented nothing histologically except the changes of phlebitis. Bacteriological study showed absence of secondary infection. The phlebitis could only be attributed to the rheumatism in this instance. There was endocarditis. The authors stated that only sixteen cases of rheumatic phlebitis had been authenticated: in only two had autopsy been made, in only one with both histological and bacteriological study.

DR. G. ÉTIENNE reported a case of death during the course of typhoid fever in a man aged eighteen, in which autopsy showed thrombosis of the large coronary vein, histological study leaving no doubt as to the nature of the lesion.

Thrombosis of the Inferior Vena Cava.—DRS.

HAUSHALTER and ÉTIENNE reported three cases of thrombosis of the inferior vena cava producing only slight symptoms. The explanation was, as proven by autopsy, that the peripheral veins remained free to carry the blood back to the general circulation. In cases in which the peripheral veins are involved one sees œdema, and involvement of the small veins of the nerves causes pain, the case then showing the syndrome phlegmasia alba dolens. These three patients were tuberculous, a condition which sometimes led to phlebitis and venous coagulation by proximity of infected and enlarged glands.

A Case of Enderteritis Obliterans.—DR. A. HEYDENREICH described a case of obliterating endarteritis which first involved the toes, then the fingers, causing the nails to fall, producing pain, dry and humid gangrene, disappearance of the pulse. The disease continued to extend for five years and a half, involving the femorals, etc., and finally proving fatal by occlusion of the coronary arteries.

Meningism and Mental Confusion.—DRS. J. SÉGLAS and E. DUPRÉ made such a classification of cases of mental confusion frequently seen in infections, intoxications, etc., presenting some of the symptoms of meningitis, but without the lesions of this disease.

Trophic Changes in the Teeth in Hysterical Subjects.—DR. PAUL SOLLIER reported two cases of trophic changes in the teeth with rapid erosion and pain, in hysterical persons.

Hysterical Hemiplegia and Mutism.—DR. FERRIER related the case, which occurred in a soldier, and stated that it was not exceptional for hysteria, like other hereditary taints, to manifest itself in young soldiers subjected to change of habit, to fatigue, and to homesickness. In the present case the man had served two years and a half.

Changes in the Cord and Nerve Roots in Typhoid Fever.—DR. VOINOT, of Nancy, had examined the spinal cord and roots of the nerves in ten cases of typhoid fever, and in all had found pathological changes in the myelin, in the axis cylinder, and in the nerve cells, but never in the connective tissue, neuroglia, nor blood-vessels.

Antistaphylococcic Immunization and Orrhotherapy.—DR. CAPMAN, of Montpellier, gave an account of his experiments in this direction on dogs, rabbits, and other animals. He had been only moderately successful.

Addison's Disease with Congenital Absence of the Suprarenal Capsules.—DR. A. RISPAL reported a case of Addison's disease in which autopsy revealed congenital absence of the suprarenal capsules. No other lesions were found. Only two similar cases had

been reported. The patient was twenty-four years of age, the symptoms of Addison's disease—melanoderma, pains, wasting, cachexia, progressive asthenia, gastro-intestinal disturbance—proved fatal in ten months.

Nail Favus.—ROSE and GALAVIELLE reported some studies of trichophytic onychomycosis, which led SABRAZÈS to say that he was first to demonstrate by cultures and inoculation the causal diagnosis of the affection. In two cases of favus of the nails he had made cultures which, when inoculated into mice, caused death.

Diagnostic Value of the Cerebro-Spinal Fluid.—DR. G. DENIGÈS and J. SABRAZÈS, of Bordeaux. Out of fourteen cases of lumbar puncture the result was positive in eight. Of the eight cases six were acute tuberculous meningitis, one epilepsy, one hydrophobia. The fluid was never clear, sometimes bloody in meningitis, while in other cases, as hydrophobia, it might come out clear. Three times in tuberculosis Koch's bacillus was very numerous in the fluid. In the case of hydrophobia the fluid injected under the dura mater of the dog caused violent rabies after two months. Chemically the fluids differed in the several cases, and the authors thought further study might result in the discovery of a formula corresponding to each type of meningeal infection.

Thyroid Treatment of Myxœdema.—DR. SIMON presented a child, aged five years, with congenital myxœdema, which had increased perceptibly in height and shown general improvement during two months' thyroid medication.

Auscultatory Sounds in Pleurisy.—DR. HERVOUEX expressed the view in this paper that the pleuritic souffle and egophony informed us of the state of the lung, not of the pleura and pleuritic effusion. If compression of the lung by fluid were the cause, these sounds should always be present in pleuritic effusion, but they were not.

Simulation of Pulmonary Tuberculosis by Certain Acute Bronchial Infections.—DR. E. CASSAET emphasized the importance of bacteriological control to clinical diagnosis of acute affections of the bronchi and lungs.

The Pathology and Clinical Varieties of Paludal Ascites.—DR. H. DE BRUN, of Beyroot, read a paper with this title, in which he held that paludal or malarial ascites was seen under two very different conditions, namely, with and without other collections of fluid or œdema. Usually there was more or less general anasarca. It was to the rare form that he directed attention. Pathologically there were three sets of cases: 1, with paludal atrophy of the liver, of which he cited two cases; 2, with perisplenitis and great pain in the hypertrophied organ; 3, with peritoneal congestion analogous to pulmonary, renal, and splenic congestion preceding paludal sclerosis.

Phosphatic Calculus in the Stomach.—DR. GARNIER presented a voluminous phosphatic calculus found in the stomach—entirely too large to have passed up from the intestine through the pylorus.

Ovarian Medication.—DRS. SPILLMAN and G. ÉTIENNE had employed ovarian medication in six cases of chlorosis. With the first dose all the patients had marked abdominal pain, headache, vague muscular pains; two had some elevation of the temperature. Three of the patients soon showed marked improvement, and in two the suppressed menses returned. The authors thought the treatment favored elimination of toxins, and in introducing an antitoxic principle seemed to act favorably on the general health, to increase the number of blood globules, and to re-establish menstruation.

Treatment of Diabetic Arthritism by Dosage of Alimentation.—DR. E. MAUREL had treated sixteen

diabetics with arthritic manifestations by food dosage, ten cases resulting in recovery, the other six in marked improvement. The treatment was equally important in other forms of joint affection.

DR. MOSSÉ gave experience with the administration of antipyrin, pancreas extract, etc., in diabetes, which was not very satisfactory. He had found a regulation of the diet the most important part of treatment.

Upon a Tremor Combined with the Cheyne-Stokes Respiratory Rhythm.—DR. PIC, of Lyons, reported a case of uræmia which had enabled him to study the pathogenesis of periodic respiration, going to confirm the view of Pachon, that the cerebral cortex participated in the production of the Cheyne-Stokes phenomenon.

The Prognosis of the Albuminurias.—This subject was treated of in two reports, one made by DR. X. ARNOZAN, the other by DR. CH. TALAMON, followed by a discussion participated in by DRS. TEISSIER, BARD, CROCQ, MAUREL, GARNIER, SCHMIDT, LINOSSIER, and others. DR. TALAMON, as reporter, stated that the elements of prognosis in albuminuria should be looked for in (1) the character of the albuminuria itself; (2) the composition of the urinary medium; (3) the etiological or pathogenic conditions of the albuminuria; (4) the special and general condition of the patient; (5) the conditions associated with the renal lesion. He considered these five divisions separately.

DR. LINOSSIER said with regard to the character of the precipitate by the cold nitric-acid test that usually slow formation of the ring, its lesser opacity, its greater diffusion, its formation in the upper part of the fluid, were signs of a favorable prognosis.

Treatment of Rheumatism by Applications of Methyl Salicylate.—DRS. LANNOIS and LINOSSIER had employed methyl salicylate locally in the different forms of rheumatism and in various painful peripheral affections, such as neuralgias, etc. In these various affections they had found the action beneficial in varying degree according to the case and condition. In rheumatism it was as useful, often more useful, than when taken internally, and avoided disturbance of the stomach. In the acute attack the pain might prevent rubbing it in and make oral administration necessary.

The Anatomical and Clinical Significance of Polyvisceral Interstitial Inflammations.—DR. BARD read a paper on this subject. He said that the presence of scleroses in conjunction with the cardiopathies presumed inflammations, subacute and interstitial. In cardiac œdema with chronic thickening the condition was one of interstitial dermatitis. These were local inflammations, and not stases which gave rise to scleroses. Ischæmic atrophies differed from scleroses connected with arteritis of inflammatory nature. Aside from the lesions of arterial origin, there were scleroses due to inflammations primarily affecting the interstitial tissue. These inflammations were polyvisceral, and the symptoms depended upon the lesions themselves, their association, and the organs affected. Briefly, inflammations were necessary to produce true interstitial scleroses which increased the weight of the organs; these inflammations were not always of arterial origin, but often were primarily interstitial.

Application of the Roentgen Rays to the Medical Sciences.—DRS. BARTHÉLEMY and OUDIN first gave an historical review and presented photographs of their own work, showing the progress made during the few months since Roentgen's discovery. Much depended upon the details of technique. For instance, Thompson's tube was better adapted to deeply seated organs in the adult, while Collardeau's gave remarkable results in fineness of details for the adult extremities and bodies of infants. The time required had been so reduced that the method was applicable even

to infants and others who could not remain long immobile. Their first photographs showed only the bony skeleton, while later ones showed also muscle-bundles, their tendinous insertion, and the nails with the bones back of them.

DR. VEDEL showed an x-ray photograph which had enabled him to differentiate between pseudo-osteo-arthritis and true osteo-arthritis, the case illustrating the former condition.

Treatment of Affections of the Respiratory Passages by Warm Baths.—DR. LEMOINE had treated and cured sixty cases of affections of the respiratory passages, such as inflammations of the tubes and lungs, etc., with baths of temperature of 37.5° C. Cold baths should not be used in these cases, however effectual they might be in typhoid. Spillmann, Bard, and Cassaet, on the other hand, had found the cold bath sometimes useful, especially the first two or three days of acute inflammation.

A Case of Labio-Glosso-Laryngeal Paralysis of Cerebral Origin.—DRS. PICOT and HOBBS, of Bordeaux, gave the history and autopsy in the case of a man, aged sixty-six, who had had several apoplectic strokes, and three months before admission to the hospital was taken suddenly with paralysis affecting the lips, tongue, pharynx, and larynx. The velum palati and muscles of mastication were not involved. The sudden and simultaneous occurrence of the paralytic symptoms led to the diagnosis of labio-glosso-laryngeal paralysis of cerebral, not bulbar, origin. The man died eight months after the accident, without noticeable progress or change in the paralysis. The autopsy confirmed the diagnosis of cerebral origin of the trouble, the bulbar origin of the cranial nerves being intact, while there were a number of small old hemorrhagic foci in the anterior and middle hemispheres, two of which had probably been the cause of the labio-glosso-laryngeal paralysis, one having destroyed on the right a part of the caudate nucleus and avant-mur, and in addition a small focus in the middle of the anterior portion of the centrum ovale on the left side.

Angina Pectoris of Bright's.—DR. RONDOT treated angina pectoris of Bright's disease by regulating urinary insufficiency.

Clinical Value of Hyperacidity of the Stomach.—DR. HERVOUET read this paper. He said that there might be a great excess of hydrochloric acid in persons not even dyspeptic. Treatment by dilute hydrochloric acid was equally efficacious in such cases and in cases of deficiency of hydrochloric acid, and did not aggravate the symptoms of the former.

DRS. AUCHÉ and CARRIÈRE read a contribution to the study of the histology of hemorrhagic effusions of the pleura. The findings differed greatly in the different cases.

Urology in Typhus.—DR. SPILLMAN, of Nancy, found in the urine in typhus albuminuria constantly, urobilinuria frequently, uric acid increased. Guérin had isolated from this urine a toxalbumin which caused diarrhœa and dyspnœa in rabbits, but not death. The urinary toxicity was diminished.

Duodenal Stenosis Simulating Pyloric Stenosis.—DR. PIC, of Lyons, related a case in which the symptoms and physical signs pointed to a hepatic colic and stenosis of the pylorus from adhesion connected with the gall bladder, the seat of stone. Laparotomy was performed and the diagnosis of the band was confirmed, but its nature remained undetermined. Gastro-enterostomy was made. Autopsy showed neoplasm of the bladder and a peritoneal band constricting the duodenum at its upper portion. The clinical picture had been one of true pyloric stenosis.

Hystero-Paludism.—DR. DUCAMP related a case of malaria in which the tremor of the chills was exaggerated and modified by the hysterical tendency of the

patient, this hysterical attack having been excited by the malaria.

A Case of Syphilitic Reinfection.—DR. FOURRIER related a case of syphilis occurring the second time fifteen years after the first attack.

DR. BARTHÉLEMY remarked that Fourrier had not proven his case by inoculation of the chancre. Syphilitic reinfection seemed not to be admitted in France; in all instances one had to do only with syphiloid or tertiary affections.

The Malarial Spleen.—DR. FERRIER gave the anatomical findings in some malarial spleens which he had had occasion to study. They related chiefly to (in two cases) the extreme abundance of small round cells, giving the cut somewhat an embryonic appearance; also to the abundance of dark pigment.

Post-Anæsthetic Paralysis.—DR. VAUTRIN reported three cases of paralysis following anæsthesia, seen by himself. One involved the deltoid, biceps, and brachialis anticus on the right side, and gradual improvement had taken place during the six years of its existence. Another was of the deltoid and long supinator on the right; the third was facial. In the last two the paralysis soon disappeared entirely. The anæsthetic used was chloroform, but the accident might follow other anæsthetics. It might be peripheral or central; in the latter hemorrhagic.

The Place of Production of Uric Acid.—DR. F. LAVAL cited the theories which had been offered as to the place of origin of uric acid in the system: one had said that it was formed in the liver, another in the spleen, a third in the blood, and finally in what one might call the leucocytic system. All these theories were correct, for uric acid was formed in the liver as well as in the kidneys, in the spleen as well as in other organs, wherever white blood cells were to be found.

Lesions of Intestinal Strangulation and Engorgement; Passage of Microbes through the Walls.—BOSE and BLANC gave results of clinical and experimental study of this subject. After stating the gross and microscopical appearances, they called attention to the close relation existing between the necrosis and hemorrhagia; hence the clinical importance of the subperitoneal ecchymosis. The transverse muscular fibres represented the most resisting part of the intestinal walls, to the importance of which fact the authors called attention. The rapid necrosis and hemorrhagia were explained in part by the action of the colon bacilli and their toxins; we knew their power to produce dilatation of the vessels, hemorrhage, and degeneration. As long as the lesions were light, without desquamation of the epithelium, no micro-organism was found either in the walls or on the peritoneum. When the lesions were more marked, micro-organisms were found in the mucous, submucous, and deeper tissues, on the peritoneum, and in small numbers in the vessels. The colon bacillus more especially was present, and combined hemorrhagia and necrosis made of the mucous and submucous tissue a veritable bouillon culture.

Multiple Neuritis Engrafted upon a Nervous Diathesis.—BERNHEIM related some experience in which multiple neuritis developed in persons of nervous diathesis. In the case of a young lady in love with a man whose father withheld consent to marriage, he was able to cure the hysterical element by hypnotic suggestion, whereas this had no effect upon the paralytic and other symptoms of multiple neuritis.

The Melbourne Hospital has two ladies on its house staff, Drs. Alfrida Hilda Gamble and Janet Lindsay Greig, who won their appointment by ranking among the highest six graduates in the final honor list of Melbourne University Medical School.

Clinical Department.

TREATMENT OF OLD DISLOCATIONS OF THE ELBOW.

By W. J. WELSH, M.D.,

BAILEY, MO.

In districts where the practice of medicine and surgery is regulated by laws rigidly enforced, old dislocations are extremely uncommon, but in districts where quacks and uneducated men do much practice such cases are common. We know how difficult it is to reduce dislocation of the elbow, even under anæsthesia when a few hours have elapsed since the accident. When a week or two or a month has passed and the dislocation remains unreduced, it is exceedingly difficult, and when several months have elapsed without correction of the deformity it is almost impossible in most cases, and it may be dangerous to use much force.

The dangers of using much force are patent to all, and if the pulleys be employed, the surgeon is liable to use more force than is justifiable before he realizes it, and he may suddenly do irreparable damage, even when he thinks he has employed but little force. In old cases in which the radius and ulna are dislocated backward the surgeon may have force applied, and in a right direction. He may skilfully use every possible manipulative effort. He may think he has nearly accomplished his object and that just in one moment more all will be right, but the more power he uses in a right direction, the more plainly and beautifully aggravating does the tendon of the triceps stand out, showing that the object cannot be accomplished in this way. In such cases it is rash to use much force. It is plain to be seen that the olecranon is the offending member. Excellent writers on the subject have advised subcutaneous section of the tendon of the triceps. This, however, is a dangerous proceeding and may be disappointing. No knowledge of anatomy that the surgeon may possess can make the operation a safe one. Any one who has seen the inside of such a joint and surrounding tissues, and noted the number and strangely diverse adhesions and changes in the parts, may well shudder at the possibilities of doing such work in the dark. It has long seemed to me that the better plan is to cut into the joint, sever the tendon of the triceps, remove the olecranon, dissect them both out, and then by proper and careful manipulation to bring the radius and ulna forward into their proper places and retain them there with the view of establishing ankylosis. I have had an opportunity of seeing this carried into effect. Miss M—, aged sixteen years, had been thrown from a horse; the radius and ulna of the left arm were dislocated backward. The accident had occurred six months before she was seen by the members of the Crocker District Medical Society. The lower end of the humerus could be seen in front of the ulna and radius: the arm was stiff and useless, was straight, could not be flexed one particle, and was only in the way. As she was an orphan the society agreed to take her under its protection and see what could be done. The pulleys were first thoroughly and skilfully applied, but all efforts failed. Subcutaneous section was considered dangerous. Three or four of the members agreed to cut down on the tendon of the triceps and olecranon and remove them. Under anæsthesia every justifiable effort was again made with pulleys and manipulation, without avail. The joint was cut into and the olecranon and tendon of the triceps were removed, thorough antiseptic precautions being observed. The radius and ulna were brought forward

and the bones set at right angles to the humerus. The following day the patient was found to be doing well. The arm was put up in plaster-of-Paris dressing. The case progressed nicely. The operation was done March, 1893. I saw the patient the following August. She was working at her vocation of housekeeping; could wash, iron, and do all kinds of housework; could put her hand on top of her head; could fasten pins and buttons with it. In short, the arm was apparently as useful a member as could be desired. As none of the members of the society had ever seen the operation before, it was practically an experiment which resulted in a brilliant success. No one who has not seen a straight stiff arm from such a cause can appreciate the deformity and unpleasantness resulting from such a misfortune. The limb is useless and only in the way, and the patient is rendered miserable. If the deformity cannot be remedied, the patient would be better off with the limb removed.

In drawing the radius and ulna forward into their proper places, one thing should be foremost in the mind of the surgeon, and that is to draw the bones fully forward and upward into their old relations. The radius should be brought well up past the lower end of the humerus and the ulna well up in front. The joint should be set at a slightly acute angle and the limb put up in a plaster-of-Paris dressing. The limb should be kept in permanent dressing until firm adhesions have taken place. If the radius and ulna have been well drawn up in front of the condyles of the humerus and retained there for a long time, the adhesions that take place will go far toward replacing the support which the tendon of the triceps formerly gave.

Intractable ankylosis need not be feared, as time and use will largely restore the functions of the limb, including the rotary movement of the forearm. The joint will be strong and will regain most of its former functions.

CONGENITAL IRREDUCIBLE UMBILICAL HERNIA.

By JAMES HARVEY RAYMOND, M.D.,

WAILUKU, H. I.

On April 3, 1896, I was called to attend a Portuguese woman, aged thirty-two, a primipara, poorly nourished, who had been delivered a few hours before my arrival by a midwife. Nothing could be learned of her previous history nor of her family history. The midwife had forcibly extracted a portion of the placenta, leaving the remainder in the uterus. The patient was anæsthetized and upon careful examination a large interstitial fibro-myoma was discovered. I carefully curetted the uterus and flushed it out with a solution of boric acid, and the patient was then taken to the Malulani Hospital, where antiseptic douches were given twice daily and stimulants were regularly administered. Recovery was uninterrupted and she was discharged fifteen days later.

My attention was called on the day of delivery to the peculiar condition of the child, which had a large hard swelling in the umbilical region, covered with the dilated parietal peritoneum, to which the cord was attached. I incised the membrane and found the swelling to be the entire liver, enlarged to such an extent as to be absolutely irreducible.

The child died shortly after the operation. The weight of the child was two thousand and forty-one grams; that of the liver one hundred and thirteen grams. The diameter of the child's thorax at the base was nine centimetres. The transverse diameter of the liver was six centimetres.

"MALARIAL HÆMATURIA."

By LUKE FLEMING, M.D.

TARRYTOWN, N. Y.

HAVING read in the *MEDICAL RECORD* of August 8th an article by Dr. Bush on "Malarial Hæmaturia, or Hemorrhagic Fever," I am anxious to give a report of a case which may in connection with the above article be interesting. In July, 1895, I was called to see Mary C—, a domestic, aged forty-two, who was suffering from malarial fever, in which the chief symptoms were a severe purpura hæmorrhagica covering the greater surface of the body, together with severe hemorrhage from the buccal and vaginal mucous membranes. Her family history was unreliable. Her own history was that for three or four days previous to my visit she had been suffering from chills, pains, and sweats. Twenty-four hours before my visit she had taken fifteen grains of quinine and shortly after this the above hemorrhagic symptoms appeared. Quinine in large doses was stopped and small doses of Warburg's tincture with arsenic were substituted. Under this treatment she recovered after a convalescence of two weeks. Five months later I was again called to see her and found her in a condition similar to that in which I found her at my first visit. Questioning elicited the fact that she had again attempted to "break up" a malarial chill by quinine and that the hemorrhage had not appeared until after the drug had been taken. Under the previous treatment she recovered. This summer I was called to see her for the third time. Now she was suffering from malaria but had taken no quinine. Wishing to test the case, I prescribed quinine and the hemorrhage appeared. I then substituted methylene blue, and she recovered. Now, with this case in mind, I am led to inquire whether the cases of so-called hemorrhagic fevers of Dr. Bush may not have been pure malarial fevers complicated by treatment.

REPORT OF A LAPARO-SPLENECTOMY.¹

By B. HATCHETT, M.D.,

FORT SMITH, ARK.

I REPORT the following case because of the infrequency of the operation of splenectomy, and hence to some degree its general interest.

Mrs. N. E. B—, a native of Arkansas, now a citizen of South Canadian, I. T., applied for treatment, August 5, 1895, and was admitted to St. John's Hospital. Her clinical history, as she told it, was that she was thirty-five years old, married eighteen years, and had nine children. She had one premature birth four years ago, from which time she dated the beginning of her ill health, though she had borne one child to full term since. She had been confined to bed with fever and pain for four months previous to my seeing her.

Six years ago she had an enlarged spleen which gave her considerable trouble, but recovered with treatment. Two years later, and soon after her miscarriage, she noticed a small tumor low down in her abdomen in the median line. It gave but little pain and grew slowly until she was stricken down with fever, when its growth became rapid and caused much distress.

At the time of my first examination the patient was exceedingly feeble, anæmic, and nervous. Temperature 103° F. Her abdomen was considerably distended and painful to touch at all points, evidencing the existence of a diffused peritonitis.

A large, round, semi-resilient tumor prominently

projected from a low position in the pelvis. Diagnosis as to the character of tumor was doubtful, but the opinion was given that it was ovarian in origin. Her condition was by no means favorable for immediate operation, and as I was on the point of leaving the city for a vacation, Dr. L. L. Saunders kindly undertook the task of caring for her for one month, and succeeded in improving her general state greatly, though she still had fever and peritonitis.

Operation, September 3, 1895. Under A. C. E. mixture narcosis, a median incision was made below the umbilicus, when the tumor was recognized as the spleen. The incision was then prolonged, adhesions were broken loose, and the enlarged organ was delivered from the pelvis and lifted into the wound. The pedicle was long and easily handled, with no loss of blood. It was transfixed with a Crawford needle, and the two halves separately ligated with strong braided silk; a clamp was applied at a more distal point, and the removal completed by cutting between ligation and clamp with strong scissors.

The stump was sterilized, found to be safe from hemorrhage, and dropped into the abdominal cavity. The usual laparotomy toilet was carefully made, and the patient came out of the ordeal as well as could be desired.

The extirpated spleen weighed six pounds. Its surface was of a dark slate color, dotted over at various points with cystic accumulations of sero-purulent fluid. The capsule was easily torn and showed the pulp and trabeculae of the organ to be very much disorganized, broken down, and presenting that condition of degeneration which has been designated as "splenic mud." Under the microscope this brownish-purple substance, or "mud," was shown to be composed largely of dark granules, granular bodies, and broken-down extravasated blood cells.

The same material was found thickly coating the internal walls of the large blood-vessels at the point where they were severed in the pedicle.

The patient did as well after the operation as one could wish after the most simple laparotomy. Her temperature began to decline almost at once, and never ran higher than 99° F. after the third day. Pain subsided, peritonitis gave way, appetite returned, and a general feeling of comfort was enjoyed during the days of convalescence. The sutures in the abdominal wound were removed on the ninth day with no sign of pus—not even the smallest stitch-hole abscess. She walked on the thirteenth day after the operation, and on the eighteenth day left for home feeling quite well, with improved complexion, appetite, digestion, etc.

On October 6th, two weeks after her discharge, I had a letter from Mrs. B—, stating that she weighed ninety-three pounds on reaching home, and that her weight was one hundred and three at writing. She had had a little fever at different times, and an occasional sharp pain in her abdomen.

November 10th, a month later, she wrote that her weight was one hundred and twenty-five pounds, and complexion good; there was some pain in the lower abdomen.

A few days ago, being nine months since the operation, I had the following letter from my patient:

"Your inquiry about my health has been received. In reply I will state that I am in better health than I have been for ten years, and as well as I ever was in my life. My appetite is good and my complexion is clear. I have no pains as a result of my former ailment, and can speak only words of praise and thankfulness for my recovery."

I made several microscopical examinations of this woman's blood, and found the relative proportion of the red and white corpuscles but little if any more disturbed than would ordinarily occur in any simple

¹ Extract from a paper, "Reports of Cases of Abdominal Lesions," read before the Arkansas Medical Society, May 1, 1896.

anæmic condition. Lukæmia was thus shown to be absent, and hence the exceedingly good results obtained, for I believe most operations prove rapidly fatal when the lukæmic state exists.

Unfortunately, our knowledge of the physiology of the spleen is still left in a state of confusion, and hence the discussion of the propriety of its removal under various conditions is unsatisfactory. The statistics of the comparatively few operations so far recorded are not encouraging.

ADHESIONS OF THE MENINGES FOLLOWING CEREBRO-SPINAL FEVER.

By MARY JORDAN FINLEY, M.D.,

MANSFIELD, O.

DR. J. LEWIS SMITH says in his article on cerebro-spinal fever in "Cyclopedia of Diseases of Children:" "No post-mortem examinations, so far as I am aware, have yet revealed the state of the brain and its meninges in those who have had this malady at some former time and recovered; whether there may not be some traces of it that are permanent, as opacity or adhesions."

The following notes of a case occurring twelve years ago and of autopsy made after death from suicide a few weeks since may be of value. I regret that they are not more full.

On March 17, 1884, I was called to see Thomas J. Kellar, aged thirty-eight years, suffering from a well-marked attack of cerebro-spinal fever, which was at that time rather prevalent here, as it has been twice since, once in 1889 and at the present time.

There were intense pain in the head, nausea, and vomiting; temperature was 102° F. The face was flushed and the eyes were injected; there was great restlessness. On the second day there was less pain and less fever, and the general condition seemed much better. The third day brought an exacerbation of all the symptoms: temperature, 103° F.; extreme restlessness, slight delirium, head retracted, legs drawn up but contraction not marked. There was a sparse eruption on the face and trunk resembling roseola.

On the fourth day temperature was lower; restlessness and delirium had given place to a stupor, from which the patient could be easily aroused, when he complained of pain in legs and general hyperæsthesia.

Improvement continued until the sixth day, when pain in the head was again very severe.

After this improvement was steady, and by the end of the second week convalescence was well established and my visits ceased. The case went on to an apparently complete recovery, leaving neither mental nor physical change.

The man was lazy, worthless, and a periodic drinker after his illness, as he had been before it, and managed to live on his pension and his wits, just as before. The pension had been granted for a crippled hand.

In the last year he had had fits of depression after his sprees, and in one of these, on the 28th of April, he shot himself through the head. The following description of the brain and meninges is taken from the report of the autopsy by Drs. John E. Speer and John Stevens: "The membranes were adherent to the brain along the crest of both hemispheres for a space half an inch wide and between three and four inches long. On these spots the dura mater, arachnoid, pia mater, and brain were closely connected with old white cicatricial tissue, which had to be cut way with the knife. There was some opacity of the arachnoid in the region near to the adhesions. There was no evidence of recent inflammatory action."

SLIGHT RESULTS OF A SEVERE INJURY.

By ROBERT H. McNAIR, M.D.,

NEW HAVEN, CONN.

I WAS called on March 25th to attend a case of apparently serious and extensive injury to the testes. The patient, J. G——, aged fifty-two, while using a piece of lead pipe as a lever and standing astride of the same, was thrown with considerable violence into the air by the end of the pipe, which in making its ascent punctured the scrotum midway between the extremities of the testes, making a laceration two inches in length, and, passing straight upward, wounded the tunica vaginalis testis by an opening large enough to admit the end of the examining finger. There were necessarily contusion to the surrounding parts and profuse hemorrhage, and after a careful examination I thought that I should find at the next visit a scrotum about half the size of the patient's head. After controlling hemorrhage and thoroughly cleansing antiseptically, I closed the lacerations and ordered cold compresses, to be applied at frequent intervals for twenty-four hours. There was no shock and but comparatively little pain.

Upon visiting the patient the following morning I was surprised to find very slight swelling and no more inflammatory action than necessary for the repair of an injury of less consequence. There was no discomfort except soreness at the scrotal wound. The patient insisted upon resuming his duties on the fourth day after receiving the injury, and with the support of a suspensory bandage he returned to his engine on a New York express train, which necessarily kept him on his feet most of the day. He was not inconvenienced any more than would have resulted from a simple incised wound on a less delicate part. Hence the reminder again of what Dame Nature is capable of doing in her workshop, regardless of surgical interference.

STRYCHNINE IN UTERINE INERTIA.

By F. E. BEAL, M.D.,

PAPILLION, NEB.

MRS. L. M——, aged thirty-seven, married, German, farmer's wife. Previous history as follows: Oldest of family of six children, all of whom are living. No evidence of syphilitic, tuberculous, or other dyscrasie could be obtained by closest questioning. Since maturity she has weighed about one hundred and fifty pounds and has always been a hard worker. She was married at the age of thirty, since which time she has had five children at three confinements: twins at the age of thirty-one; single at the age of thirty-three; and again twins at the age of thirty-five. Of these but one child was born alive, one of the twins of the first birth. All of these labors were characterized by absolute inertia of the womb and excessive hemorrhage during the entire three stages of labor, and even the following two and two and a half days, necessitating the constant attention of from one to three physicians, who had to use the most heroic measures to keep the patient from bleeding to death. All of her children have had to be taken by high instrumental delivery, simply because of the absolute absence of uterine contractions, and for the same reason each placenta has had to be delivered by the hand thrust into the uterus. Both husband and wife being quite intelligent, they gave me a good description of the treatment that had been employed, and assured me that the mother had faithfully taken ergot both internally and subcutaneously to its fullest extent, quinine, etc., to promote labor pains, but in vain. The bleeding, especially that post partum, could be

controlled only in a degree by active and repeated applications of styptics within the womb.

On May 25th I was called seven miles into the country to attend her in her fourth confinement. I knew nothing about the nature of the case when called, getting the above history at the time and since. I found the woman in a semi-faint: there was a pronounced general relaxation over the entire body; the pulse was 106 and weak; the pupils were dilated; the lower extremities were cold and clammy. Vaginal examination disclosed a large flabby os about two-thirds dilated; the position of the child was normal. The woman had been bleeding rather profusely for two hours, the hemorrhage having begun suddenly on the expulsion of the amniotic fluid. There was entire absence of pain and uterine contractions, the walls of the womb being soft and flabby, and all manipulation seemed only to increase the flow of blood.

Being, of course, averse to using ergot before the completion of the third stage of labor, and being assured by all present that the woman was in exactly the same state as she had been each time before, and that neither ergot nor any other medicine would do her any good, I determined to try strychnine in large doses subcutaneously. I immediately injected one-tenth grain of strychnine sulphate into the arm and in half an hour the bleeding had ceased; the pulse rose to 96 and became stronger, and the uterine pains were present enough to make the woman complain. Those present asserted that it was the first time she ever had a labor pain. Four hours from the first injection I repeated with one-twentieth grain, because the pains, while regular, were not of sufficient force. At the end of eight hours from the first injection she was delivered of a healthy eight-pound boy, the placenta being expelled with a good hard afterpain in eight minutes after the birth of the child. There was no post-partum hemorrhage, the uterus contracting nicely and remaining contracted. In short, it has never been my good fortune to meet with a labor and entire puerperium that were more entirely normal—after the first injection of strychnine.

Surgical Suggestions.

The Tourniquet.—When a rubber tourniquet is applied to the thigh, care should be taken to use a wide rubber band and not a rubber tube, since cumulative pressure of the rubber tubing is sometimes great enough to injure the nerve.—DR. WYETH, *International Journal of Surgery*.

Ulcers of Leg.—

R. Acidi carbol.....	2	parts.
Acidi borici	10	"
Pulv. camphor.....	7½	"
Ichthyol	20	"
Ol. andropogon nardi	q.s.	
Ung. zinci oxidi	q.s. ad 100	"
S. Apply once a day.		

—EDLEN, *New York Medical Journal*.

Malignant Tumors.—Dr. Senn says the essential features of the modern treatment of malignant tumors may be summed up as follows: "Operate early and thoroughly. The treatment of unoperable sarcoma by injections of the sterilized toxins of the streptococcus of erysipelas and the bacillus prodigiosus has not had the expected results."

Empyema of Antrum of Highmore.—Dr. Cobb (*Boston Medical and Surgical Journal*, May 7th) writes that Dr. Mackenzie has suggested that the pus discharge be examined for bacilli. This has been done, with no important results as regards diagnosis. The

staphylococcus pyogenes aureus, albus, and citreus, and the pneumococcus of Télamon-Fraenkel have been found. The latter is of interest, as pneumonia has followed antral disease.

Abscess of Ovary.—Dr. J. H. Etheridge (*American Journal of Medical Sciences*, April, 1896) reports three cases of abscess of ovary due to pneumococcus. So far as could be ascertained, no case of ovarian abscess produced by this microbe has been reported previously. "The majority of abscesses of the ovary are the work of the staphylococcus. A few ovarian abscesses contain the colon bacillus."

Continuous Submersion.—Dr. Hodges writes in the *Journal of the American Medical Association*, April 25, 1896, as follows:

1. Continuous submersion is harmless. 2. Continuous submersion will almost instantly limit infectious gangrene and control septicæmia and sapremia. 3. Continuous submersion will quickly relieve the pain and discomfort of phlegmonous inflammation or cellulitis. 4. Continuous submersion will speedily reduce temperature and pulse and overcome the consequent depression of the patient's vital forces.

Mixed Infection.—A fact of practical importance to the surgeon is that an area infected by one form of pathogenic organism may be invaded by another form. This is known as a mixed infection, and consists of a primary infection with one organism and a secondary infection with another. Koch found both bacilli and micrococci in the same lesion of tubercle. A soil filled with pneumococci is favorable to the growth of pus cocci and tubercle bacilli. Tuberculous and syphilitic lesions may be attacked by erysipelas. Chancre and chancroid may exist together. A syphilitic ulcer is a good culture ground for tubercle bacilli (Schnitzler). Suppuration in lesions of tuberculosis means a secondary infection with pus cocci.—DR. DA COSTA, *Manual of Modern Surgery*, p. 30.

Prevalence of Trachoma.—Dr. Van Millingen, of Constantinople, reports in the *Annales d'Oculistique*, vol. cxix., No. 3, that from an extended study of the subject and correspondence with ophthalmic surgeons in all parts of the world he has reached the following conclusions: 1. Trachoma is an infectious and contagious disease, which predominates in uncivilized countries and tends to disappear with the progress of hygiene. Hygiene and cleanliness are the best preservatives against trachoma. 2. Trachoma is not influenced by altitude: it may spread wherever people are uncleanly and live in poverty quite as easily at altitudes of from 1,000 to 5,000 metres as on plains. 3. All races are equally susceptible. An immunity for certain races does not exist.

Circumstances under which Chloroform is Preferable to Ether.—Though it is settled beyond a doubt that chloroform is more dangerous as an anæsthetic than ether, Dr. George W. Gay, of Boston, in discussing the question concludes that chloroform should be used in the following diseases and conditions: All cases requiring tracheotomy or œsophagotomy: as membranous croup, laryngitis, acute, chronic, traumatic, specific, or tuberculous; œdema of larynx and glottis; malignant disease of the throat and neck; deep cervical cellulitis; deep tumors of the neck, as bronchocele; foreign bodies in the air passages or œsophagus; bronchitis in the aged; and asthma. Dr. Gay admits that there may be other cases also in which chloroform is preferable.

After-Treatment of Tracheotomy Cases of Membranous Croup.—Dr. R. M. Harbin, of Rome, draws the following conclusions in a discussion of the above

subject at a meeting of the Medical Association of Georgia.

1. Croup, whether diphtheritic or membranous, is almost invariably fatal without surgical treatment, and the few cases in which patients recover by medicinal treatment alone are not to be considered. 2. So far as the practical indications for tracheotomy are concerned, it makes no difference whether croup be diphtheritic or membranous. 3. Tracheotomy has the advantage over intubation, in that it gives a better means of expectorating the membranes and furnishes free drainage from the site of septic infection. 4. Tracheotomy is a justifiable surgical procedure and should be performed in all cases where our therapeutic resources have been exhausted, and when the patient is in imminent danger of suffocation. It should be done in hopeless cases, since it either offers a chance for the patient or promotes euthanasia. 5. Tracheotomy keeps the patient alive until the pseudo-membrane disintegrates and resolves into a muco-purulent liquid and is expectorated through the tube. 6. The after-treatment is the most important part of the procedure, and the author attributes the successful results reported to the persistent use of limewater.

Partial Convulsions Occurring Prior to Delivery.

—Emory Lamphear, M.D., Ph.D. (*American Journal of Surgery and Gynecology*, April, 1896) makes the following rules: 1st, chloroform the patient; 2d, send for an assistant, if possible to get one quickly; if not, let the husband or some one else give the chloroform under close watching, as extreme haste is necessary; 3d, empty the uterus at once; the prime object is immediate delivery of the fetus. The practice Dr. Lamphear follows is this: If the os be dilating and dilatable, he rapidly enlarges the opening until the long forceps can be applied to the engaging head, or the hand can be introduced to perform version and speedy delivery. Often this can be done inside of a half-hour. If not, then the proper thing to do is to cut the cervix freely upon each side up to the cervico-vaginal junction, thus producing an artificial double laceration of the cervix uteri. Care must be taken not to cut through the vaginal wall. If the outlet is very close, as in primiparae, he cuts even through the perineum, but not through the muscle near the anus. As soon as he removes the placenta, the os is caught and pulled down, so as to allow six or more catgut sutures to be introduced in the cuts in the cervix. If the perineum be injured, it is sewed, irrigation practised, and then the anæsthesia is discontinued.

Vertebral Caries.—Dr. Thorburn (*American Journal of the Medical Sciences*, May, 1895) gives the following indications for operation:

(1) A steady increase in symptoms in spite of favorable conditions and treatment. (2) The presence of symptoms which directly threaten life. (3) The persistence of symptoms in spite of complete rest is the indication which has been most generally adopted. (4) In posterior caries (caries of the arches) operation is clearly indicated, as here we can readily both treat the paraplegia and remove the whole of the tuberculous tissue. (5) The existence of severe pain, if the patient is being exhausted thereby. (6) Children, as a rule, yield better results than do adults.

Subclavian Aneurisms.—Of 115 cases of all sorts, 79 presented complications (about 60 per cent.), of which 17 recovered (about 19 per cent.).

(1) Hemorrhage occurred in 48, of which 10 recovered (about 20 per cent.). (2) Inflammation, supuration, sepsis occurred in 15, of which 5 recovered (33 per cent.). (3) Pleuritis, pneumonia, pericarditis, bronchitis occurred 7 times, and they all died. (4) Phlebitis occurred in 2 cases, of which 1 recovered. (5) Cerebral symptoms in 5 cases, and they all died.

(6) Gangrene occurred in 4 cases, of which three recovered (75 per cent.). (7) Penetration of air in veins occurred in 1 case in external jugular vein; it recovered. (8) Wound of thoracic duct occurred in 1 case; it recovered. (9) Wound of pleura occurred in 1 case; it recovered. (10) Shock in 1; it died.—*Annals of Surgery*, December, 1895.

Cancer of the Breast.—Drs. Thomas Jones and John E. Platt present in *The Lancet*, August 31, 1895, p. 522, the following conclusions in regard to results of operations:

(1) Cancer of the breast, although a formidable disease, is amenable to treatment by operation, and the proportion of cures so obtained may confidently be put down at twelve per cent. (2) Non-success after operation is very frequently due to the extensive character of the disease when it first comes under observation; probably if relief were sought earlier, a much larger proportion of cures could be obtained. (3) Moderate enlargement of the axillary glands is no bar to operation or to a successful issue, provided they are systematically and carefully removed, and the axillary space thoroughly cleared. (4) It is well-nigh impossible to discover trifling enlargement of the axillary glands by an examination through the unbroken skin. (5) No operation for removal of cancer of the breast can be considered complete unless the axilla be examined through the wound, the additional risks of such a procedure being very slight. (6) The large number of cases in which recurrence occurs locally points to the necessity of very free removal of the disease; all doubtful skin must be taken away and great care must be exercised not to leave any outlying portions of breast tissue. (7) Operation is contraindicated when the whole of the growth cannot be removed or when the supraclavicular glands are enlarged. The only condition which might render an operation justifiable under such circumstances would be the presence of a foul cancerous ulcer, the removal of which is desirable on account of the great inconvenience which it occasions.

Furor Secandi.—It would seem that every tyro imagines that surgery offers the quickest route to success, and that fame is to be attained only through blood. Hence every case the symptoms of which are directed to McBurney's point is necessarily a case of appendicitis, for which the only sovereign remedy is the knife; or, if it be a woman, and her suffering is referred to the ovarian region, or she have a fibroma, however small and barren of symptoms of importance, not only must she be subjected to cæliotomy at once, but in nine cases out of ten has her uterus or uterus and ovaries sacrificed, thus unsexing her without the slightest effort being made to spare these organs and preserve to the woman her distinguishing function.—R. BEVERLY COLE.

Cæsarean Section: Suture of the Uterus versus Total Extirpation.—Dr. Henry C. Coe (*Medical News*, May 30) says the following are the advantages that the radical operation presents: 1. Rapidity of execution. Ligation of the broad ligaments and separation of the bladder are more easily accomplished than the same steps in an ordinary hysterectomy. In one of the writer's cases of cæliotomy for rupture of the parturient uterus, clamps being used, it required only five minutes; another in which ligatures were used required ten minutes. It is not necessary to elevate the patient in Trendelenburg's posture. Time is often a very important factor. There is no more shock or loss of blood than after suture of the uterus. 2. By removing the entire uterus we are reasonably sure that no infected tissue remains. In one Porro case the patient recovered,

but the cervix, being infected, sloughed out entirely. Free drainage per vaginam may save the most desperate case. No sutures are left to give subsequent trouble. 3. Neoplasms of the ovaries, or uterus, or diseased appendages are removed at the same time. Removal of the adnexa after Cæsarean section always seems fraught with considerable danger, since the large soft stumps, with their distended veins, are exposed to more or less traction during uterine contractions. Fibroids apparently not large enough to justify a Porro operation are left behind to cause future trouble. 4. Convalescence is quite as rapid as when the uterus is sutured. Dr. Coe says that in his experience the objection with regard to weakening of the vaginal roof by removing the cervix is largely theoretical, in puerperal hysterectomy as well as in total extirpation for any cause. The writer says he has found no case of vaginal enterocele among one hundred cases of his own or those of his friends who practise total extirpation. He concludes by saying that the indications for Cæsarean section are becoming every year more clearly defined and the operation will probably be more rarely performed in the future. Total extirpation has the additional advantage of preventing the risk of a second operation.

Curettage of the Uterus.—This procedure should always precede abdominal section for the removal of the uterine appendages, because in these cases the endometrium is usually so diseased as to interfere with the recovery of the patient if this part of the operation is omitted, and because thorough cleansing of the uterus, vagina, and vulva is imperative in case vaginal drainage is required.—WATKINS, *Medical News*, August 8, 1896.

Correspondence.

LOCAL TREATMENT OF AFFECTIONS OF TRACHEA, BRONCHI, AND LUNGS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An article in your issue of August 1, 1896, by Dr. Joshua Lindley Barton, on the treatment of the above-mentioned group of affections by intratracheal injection, makes it desirable for me to publish a few words anent the topical treatment of these diseases, as I have been using it these many years.

Dr. Barton gives due credit to Horace Greene's works in 1838, when he passed a small sponge saturated with a solution of nitrate of silver through the glottis into the trachea, in lieu of which method he afterward adopted catheterism and injection of liquids into the air passages. This method required special preparation of the patient. The author justly remarks how much these endolaryngeal applications have been facilitated by laryngoscopy and the discovery of cocaine. He duly appreciates the workings of Bergeron, Pernice, Kirke, Coakley, and Joseph Muir. He recommends previous sponging of the throat, then the introduction of the laryngeal mirror and the use of Muir's syringe with laryngeal tube. He continues, verbatim: "If care is taken, when inserting the tube, to avoid touching the glosso-epiglottic or the aryteno-epiglottic folds or the interarytenoid space, each of which seems to act as a cough centre, the irritation caused by this procedure will be found to be surprisingly slight."

Now, first of all, I suppose all physicians will agree how much local treatment, as a rule, whenever it is possible, is to be preferred to internal medication. And for this reason local treatment of the above-quoted affections deserves much more attention than it has until now received. I have never tried the intro-

duction of medicated sponges or the nozzle of the laryngeal syringe. The method is not quite so easy as it would appear to be from a consideration of the passage quoted above.

For the last twelve or fifteen years I have used intratracheal injections made with a Pravaz syringe, the needle of which is inserted into the windpipe through the crico-thyroid ligament, or according to circumstances, through any accessible intercartilaginous space of the trachea. If this injection be applied in the recumbent posture of the patient, with his head slightly elevated, the injected liquid flows down the posterior surface of the trachea, causing only exceptionally any inconvenience. I really cannot understand why in laryngeal diphtheria this method is not oftener made use of for the local application of convenient remedies to the larynx.

But much oftener than these injections I have used insufflations of medicated powders, as the use of the needle is always somewhat unpleasant to the patient or family, who oppose much less the use of the insufflation tube.

The insufflations are applied once, twice, or even thrice a day, with nitrate of silver, opium, alum, cocaine, etc., always made up into a fine powder with sugar.

An obvious objection will be that a violent access of cough and strangling must necessarily follow the introduction of powder into the air passages. But not so, gentle reader. If proper care be taken that the insufflation is done just when the patient takes a deep breath, no cough will follow.

The instrument used is an india-rubber tube with a shortly curved end, which is not intended to penetrate into the larynx, but to be held in the posterior fauces, behind the root of the tongue and over the aditus laryngis. The tube is provided with a flexible rubber extension to be held between the physician's lips, and must have a big terminal opening at its laryngeal end. If the insufflation be done by means of a rubber ball, the movement of squeezing that will unavoidably change the direction of the instrument. Besides, as no laryngeal mirror is required, the physician will have one of his hands free to hold the patient's tongue, which the former will do better than the latter.

I have used these insufflations in various affections of the larynx, windpipe, and bronchial tubes, always with satisfactory and prompt results, so far as the nature of the disease will allow it. If, as in consumption, it does not cure, it alleviates that troublesome symptom, "cough."

Whether this method of insufflation is original with me or not, I am not able to say, shut off as I am from libraries and scientific intercourse. But I make no claims in that direction. I shall be contented if this method, simplified as I give it, is more generally applied. It will prove satisfactory to the physician and to his patients.

F. SEMELEDER, M.D.

CÓRDOVA, MEXICO.

A Double Expiration.—A Paris newspaper provides its subscribers with free medical attendance. Recently the manager of the paper gave notice to one of the physicians "not to prescribe for X any more: his subscription has expired." The doctor replied: "So has X."—*Tit-Bits*.

Toothache.—When patients complain almost continuously of toothache or sensitive teeth, it is usually an indication to administer the phosphate of lime.—*Dental Register*.

Gonorrhœa is claimed by Asmus to be cured in a few days by injections of an emulsion of creosote of a strength of from 0.2 to 1 per cent.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 12, 1896:

	Cases.	Deaths.
Tuberculosis.....	162	100
Typhoid fever.....	51	10
Scarlet fever.....	21	1
Cerebro-spinal meningitis.....	1	2
Measles.....	42	4
Diphtheria.....	127	24
Small-pox.....	0	0

Small-Pox in Germany claimed sixty-five thousand victims annually a century ago. Now the average number of deaths is but one hundred and fourteen a year.

The Pasteur Institute in Athens was established by Dr. Pampoukis in 1894. During the first sixteen months two hundred and one cases were treated, with but one death.

Poison Ivy is said to be antidoted by the brook balsam, spotted touch-me-not, or jewel weed (*Impatiens fulva*), which grows freely in this latitude along the banks of brooks. Its leaves and stems are bruised and applied as a poultice to the inflamed parts.

Oxygen Inhalations after Chloroform.—Dr. Landau, of Berlin, prefers chloroform to ether, provided oxygen be administered afterward. He finds that if the patient inhales oxygen for a few minutes as soon as the chloroform is withdrawn, subsequent headaches, nausea, and vomiting are avoided. Further, consciousness is more quickly restored, the pulse becomes fuller and slower, and the dusky hue of the face disappears more quickly. Physiologically this is what would be expected when the oxygen is restored to the blood. From the excellent results and freedom from danger he thinks it is the duty of the physician to try the oxygen inhalation for the relief of the unpleasant after-effects of the anæsthetic.

Prevention of Diseases and Mortality in Infancy and Childhood.—Dr. Jane L. Herson (*Journal of Medicine and Science*) recommends wrapping the newborn child with a warm blanket and holding it in an inverted position for some minutes when asphyxiation is threatened. This causes the blood in the liver (one-quarter the entire volume of blood at this time) to flow to the heart and medulla, causing a physiological stimulation of respiration. Much gastro-intestinal disease may be relieved by avoiding overfeeding or too frequent feeding. Food administered once in three or four hours is sufficient. Eye disorders may be avoided by substituting kindergarten instruction for book study until children are ten years old, and after that time by insisting that schoolrooms be properly lighted and only books with good print be used. Night study should not be required nor permitted before twelve years of age.

New Scheme for Treatment of Female Inebriates.—Lady Henry Somerset is of the opinion that nothing could be worse for habitual drunkards than the sedentary employment usually assigned to them in reformatory homes. She has obtained possession of one hundred and eighty acres of land in the town of Duxhurst, situated beyond easy reach of all drinkable forms of alcohol. She has begun the construction of a small village upon this tract. It is to consist of

scattered cottages, which the patients will occupy. There will be a hospital, a chapel, a children's home, office buildings, and laundry for general use. Six patients will occupy each cottage and they will be expected to take part in the industries which are being organized on the estate. There will be light agricultural work, poultry raising, bee keeping, dairy work, flower culture, jam making, and a small amount of needle work and washing. The idea is to put the women to work where they can see and take pride in the results of their labor. The institution cannot afford to take free patients, so there will be a minimum charge of \$1.25 per week. If a patient works out the cost of her maintenance, the amount is credited to her and handed over to her when she leaves the institution. The English public is being asked to furnish money for the development.—*New York Sun*.

Micro-Organisms in the Healthy Nose.—In a paper published in the "Medico-Chirurgical Transactions," vol. lxxviii., Drs. St. Clair Thomson and R. T. Hewlett give the results of some experiments made to determine the nature and number of micro-organisms in the healthy nose. In the entire literature of the bacteriology of the nose, they say, there are only two articles wholly devoted to the normal or physiological condition. One of these is by Dr. Jonathan Wright, the other by L. von Besser, both published in 1889. The following is a summary of the conclusions formulated by Drs. Thomson and Hewlett: (1) That in all bacterioscopic investigations of the nasal fossæ, in all researches as to the action of the nasal mucus, etc., a clear distinction must be made between the vestibule of the nose and the proper mucous cavity. The former is lined with skin and is furnished with hairs and with sudoriferous and sebaceous glands; and it is not part of the nose cavity proper, but only leads to it. (2) The neglect of this distinction may account for the discrepancies in previous observations on the subject. Contamination with the lining of the vestibule is difficult to avoid, even when this source of error has been realized. (3) In the dust and crusts of mucus and debris deposited among the vibrissæ of healthy subjects, micro-organisms are never absent. They are rarely scanty in number; as a rule they are abundant. (4) On the Schneiderian membrane the reverse is the case. They do not assert that micro-organisms are completely absent; obviously some must occasionally occur, but under normal conditions they are never plentiful; they are rarely even numerous, and in more than eighty per cent. of their observations they failed to find any, and the mucus was completely sterile. These observations were limited to the anterior part of the nose, and, as not more than a fourth of the cavity is accessible to inspection and examination, it is reasonable to conclude that germs would be found still more infrequently in the deeper portions of the fossæ. (5) The occurrence of pathogenic organisms must be so infrequent that their presence in the pituitary membrane can be regarded only as quite exceptional.

Insanity in Children.—Dr. Conrads gives a lengthy review of the subject of infantile mental derangement, which is referred to in *Pediatrics*, as follows: First, he notices the variety of insanity in children and gives an extended notice of the literature. As regards the question of the relative frequency of insanity of the two sexes in children it cannot be definitely stated with our present statistics. Among the causes heredity is first; next comes the condition of the child's bringing up, his education and training, the management by nurses by frightening their charges, the discipline and methods at school, etc. Psychic causes, fear, shame, and especially mental shock, are not to

be underestimated. Emminghaus found twenty-three per cent. of the cases he collected in the literature to be due to these causes; homesickness is not common, but cases have been known. Conrads lays some stress on the evil effects of religious excitement in predisposed older children. Contagious (mental) and epidemic influence need mention, as they have been repeatedly observed. Onanism has been undoubtedly overestimated as a cause, but in predisposed persons it may have its effects. Among the somatic causes, acute infectious fevers are first in frequency. Emminghaus found these as a cause in twenty-five per cent. of his cases. Trauma, especially of the head, insolation, exposure, etc., have all had their victims. Ear disease and dentition may affect the mental condition, and the effects of nasal disease, adenoid vegetations, and tonsillar enlargements are suggestive. Middle-ear disease has been demonstrated by Bouchut and Emminghaus as causes of infantile derangement; intestinal parasites, tuberculosis, and cardiac weakness are also factors. Hereditary syphilis is the cause of juvenile paresis; whether it acts in producing other forms of insanity is uncertain. Long-continued suppuration has been the cause of melancholia, as in one case of Conrad's own observation. Reflex psychoses, aside from those of the ear and intestinal disorders, have been observed to follow wounds, extraction of teeth, etc. Various poisons—lead, mercury, cocaine, tobacco, etc.—have caused mental disease in children as well as in adults, and alcoholic insanity has been often reported. Conrads gives briefly a case of acute hallucinatory delirium observed by him in a child of two and one-half years, from this cause. The permanent psychoses of children occur usually in degenerate individuals, who sooner or later reveal their stigmata. The first symptoms of insanity can naturally only be looked for after the conscious perceptions have become manifest in the child and must consist in aberrations of these. The earliest age at which hallucinations have been observed is fourteen and one-half months (Marce). Visual hallucinations are far the most frequent. Delusions can show themselves only after a certain stage of mental development. The types of mental disease in children fall under two heads—the pure psychoses and the forms connected with the neuroses. Of the former it is difficult to say whether mania or melancholia is most frequent in the earlier years, and both are most frequent toward puberty. Mania generally begins without the prodromal, depressed phases, runs a subacute course, and generally ends in recovery. Melancholia may assume any of its types, is commonly gradual in its onset, and is subject to remissions. Its course and prognosis are the same as mania. Suicide in children should be mentioned in this connection, and from the statistics of France and Prussia seems to be steadily on the increase. It is, however, still infrequent. Conrads, taking the proportions of adults and children in Prussia in connection with the statistics of suicide, finds that it is forty-six times less common in the latter than in the former. Periodic insanity in children is usually of the maniacal type, and, with circular insanity, has an absolutely unfavorable prognosis. But few cases of either are found in the literature. Under hallucinatory insanity, Conrads includes two types—acute hallucinatory paranoia and transitory insanity—both characterized by hallucinations, the former the more chronic and the latter the acute type. In the former occur the stuporous cases that are often confounded with melancholia. The prognosis of both, except when they succumb to exhaustion or suicide, is favorable.

Paranoia of the pure type is rare in childhood, but the degenerative prodromal stage of the original paranoia of Sander is very common. These candidates for

paranoia are usually of the male sex; in all there is a hereditary taint. They are generally quiet, sentimental, and hypochondriacal children, who are liable to feel themselves slighted by their parents, and often conceive notions of self-importance, which are the incipency of their delusions. Hypochondria is closely allied to paranoia, and while its occurrence is rather rare, and has been denied in children, it is sometimes met with and is usually a degenerative sign. Its prognosis is only favorable in the milder cases. Imperative conceptions and acts are also met with, and frequently indicate a degenerative taint, and are often connected with masturbation as an exciting cause, but they are not so serious in their prognosis. The so-called "impulsive insanity" is diagnostically indistinguishable from these impulsive acts, though it has been accepted as a special type. It is always degenerative and of unfavorable significance. Passing by what is said of idiocy, a word can be given to moral insanity. This, Conrads claims, rarely exists without some mental impairment, and sexual perversion is often present. Recovery is as improbable as in idiocy; the apparent recoveries are, perhaps, only remissions of long duration. Paresis in children has been lately reported by various authors. Its connection with hereditary syphilis has already been noted. Among the neurotic insanities, that connected with epilepsy takes the first rank. Hysteria is commoner in children than it is generally supposed, especially in girls. Hereditary is its most important etiological factor. The mental disorders of chorea consist mostly in capriciousness, irritability, and a great tendency to sudden emotional disturbances. Hallucinations, illusions, and maniacal delirium may also occur, and Leidesdorf has observed hallucinatory paranoia. Very recently Moebius has directed attention to the resemblance of choreic to toxic insanity as supporting the view that chorea may be of infectious origin.

As regards the therapy, it would be best if all cases, except the milder forms of mania and melancholia, hypochondria, and the cases of imperative conceptions, and the stuporous cases, were treated early in a special asylum, very few if any of which, unfortunately, exist for children. Prophylaxis is still more important, and should properly begin literally *ab ovo*. The marriage of degenerates, insane, drunkards, etc., is a most prolific cause of infantile insanity and idiocy. Where the tendency exists in the child, its bringing up and education must be the subject of the greatest care. Ignorant and reckless nurses, especially if given to drink, may do the greatest injury, and in no case should alcohol in any form be allowed to a child under ten years, excepting, of course, as medicine in acute infectious diseases. Special care should be given to the points of masturbation and the general habits of the child; to the possibility of nurses or others working injuriously upon its fears and imagination; to the educational methods and discipline. It would be well were teachers obliged to study mental pathology in their professional preparation.

As a summary of the points in regard to which it is desirable to direct attention in relation to the psychoses of children, Conrads concluded his paper with the following as desiderata: 1. Statistics of infantile insanity, by means of circulars of inquiry to the medical profession, as to the actual number of insane children in their knowledge. 2. Information as to relapses, by communication from medical men as to the mental disorder of persons who had been insane in childhood. These could best be obtained from family physicians, who are usually able to follow the family history back for a lengthy period. 3. Special asylums for insane children. 4. Sufficient knowledge of teachers of the psychopathic states in childhood, and greater care in schools to mentally defective children.

THE DIAGNOSTIC VALUE OF BLOOD EXAMINATIONS.

BY GEORGE P. SPRAGUE, M.D.,

DANVERS, MASS.,

ASSISTANT PHYSICIAN, DANVERS LUNATIC HOSPITAL.

ALTHOUGH Swammerdam discovered the corpuscles of the blood as early as 1658, and many others since his time have investigated its physical and chemical properties, it has been only within the past fifteen years that the blood has been carefully studied from a clinical standpoint. It is true that Virchow and Bennett and Craigie in 1845 first noted the enormous increase in white corpuscles in leukæmia, and that Duncan in 1867 recorded the decrease of hæmoglobin in chlorosis. But it was not until the discovery of the plasmodium malarie by Laveran in 1880 that a careful study of the relation of blood changes to disease processes was initiated.

This long delay in exact work was due largely to a lack of the instruments to which—coupled with the use of the differential staining qualities of aniline coloring matters—we owe most of our present knowledge of the conditions of the blood in disease.

The normal histology of the blood, as at present understood, embraces, roughly, the red biconcave discs, the white globular cells, the blood plates, and the plasma. The white cells are divided—in accordance with the way in which they stain with aniline colors—into lymphocytes, large mononuclear forms, polynuclear leucocytes, and eosinophiles. In addition to these, other forms are found in disease, the most prominent of which are the nucleated red corpuscles and a fifth variety of white cell, the myelocyte.

To make a thorough clinical analysis of the blood we must determine the number of red cells; the number of white cells; the proportion of white cells to red ones; the amount of hæmoglobin; its proportion to the number of red cells; the number of each variety of white cells and its proportion to each of the other forms of white cells, and to their combined numbers; the sizes and shapes of the cells; whether or not they contain nuclei or pigment in any form, and finally as to the presence or absence of any pathological substance floating freely in the plasma. It is along these lines that I wish to present a few facts concerning the diagnosis of disease.

The diseases in which a blood examination most naturally suggests itself are the various forms of anæmia, in many cases of which nothing else will give an early diagnosis. And by anæmia is meant not all cases in which the skin is apparently bloodless, but only those in which the amount of hæmoglobin or the number of red cells is below normal; for there are cases of persistent pallor, due perhaps to some peculiarity of the vasomotor system at the surface, in which the blood is normal.

As an illustration of the value of a blood count in anæmia may be cited the following case: Miss J., aged eighteen, blond, resembles her mother and maternal

aunt, both of whom died of phthisis. About two years ago, after nursing her father until his death, she began to lose strength, had poor appetite, slight fever, and cough, with shortness of breath on exertion. Although the fever and cough soon disappeared, she continued to lose strength, and it was feared that she had phthisis until she came under observation several months later, when it was found that she had 4,000,000 red cells per cubic millimetre, but only 36 per cent. of hæmoglobin, and although her skin was not colorless, it was plain that she had chlorosis. The daily use of carbonate of iron for three months gave a count of red cells of 6,000,000, with a hæmoglobin percentage of 84. Of course in a young girl the age usually suggests the likelihood of chlorosis in cases of gradual loss of strength with shortness of breath on exertion. It had not done so in this case, however, and in the rare cases of chlorosis in boys, this possibility is even less likely to be considered. But when in any given case in adolescents we find that the red cells are either in normal number or but slightly lessened, while the hæmoglobin is in half or in less than half the normal amount, we may safely make a diagnosis of chlorosis; and, on the other hand, we must not consider a case to be one of chlorosis unless there is this lessened proportion of hæmoglobin to red cells.

On this point Strümpell's statements that there is more or less pallor of the skin and mucous membranes as a constant and essential symptom of chlorosis, and that there is usually a decided decrease in the number of red corpuscles, are misleading. Chlorosis rubra is a well-marked form, and Osler and Thayer, Griffith, Gräber, Henry, Vierordt, Hayem, and others place the average number of red corpuscles in this disease at about eighty per cent. It may therefore be considered that the lessened hæmoglobin richness of the individual red cell is the essential diagnostic point in chlorosis.

At the opposite extreme as regards the relative proportion of red corpuscles and hæmoglobin we find pernicious anæmia. While a typical case of this latter disease, like a typical case of chlorosis, may offer but little obstacle to a correct diagnosis, many cases of it have been mistaken for chlorosis, simple anæmia, or Bright's disease.

To illustrate its resemblance to the latter may be mentioned a case occurring in the service of my colleague, Dr. Worcester, who has kindly placed this and other cases at my disposal.

Mrs. L., aged fifty-two, who has been a patient in the Danvers Lunatic Hospital since October, 1884, continued in fair bodily health until about eighteen months ago, when she began to lose color, the face appearing waxen, and to have œdema of the feet and ankles. The urine was examined, and was found to contain a small amount of albumin and a few casts. Her symptoms suggested Bright's disease. About the same time she began to have dyspnœa on slight exertion, but did not lose much or any in weight.

Soon after the close of last year she had become so yellow and short-breathed, and the ankles so œdematous, without any increase in the amount of albumin or in the number of casts, that the blood was examined, with the following result: red cells, 1,250,000 (about

25 per cent. of normal); leucocytes, 6,360, of which 5 per cent. were large mononuclear, 42 per cent. polynuclear, and 53 per cent. lymphocytes. The red cells varied from very small to very large, and many of them were irregular in shape. She had been taking iron without any improvement, but the condition of the blood, coupled with the other symptoms, pointed so strongly to pernicious anæmia that she was at once put on Fowler's solution. A hæmoglobin examination was secured soon after this and showed 30 per cent.

After six weeks of the arsenic treatment the blood count showed 1,902,000 red cells and 45 per cent. of hæmoglobin. A month later the red cells numbered 3,700,000, and the hæmoglobin showed a percentage of 60. The red cells were nearly normal in size and shape.

Bristowe thinks that no positive diagnosis between chlorosis and pernicious anæmia can be made, and Henry maintains that pernicious anæmia is simply the terminal stage of some cases of chlorosis and secondary anæmia. This position is stoutly assailed by many observers, and the argument in favor of considering it a separate disease seem to be the stronger.

Whatever the etiology, the use of iron, which is a specific in chlorosis, is rarely of advantage in pernicious anæmia, and the proportion of hæmoglobin to each red cell is usually above the normal in pernicious anæmia, while it is below the normal in chlorosis. These differences, together with the markedly altered size and shape of the red cells in pernicious anæmia, and the practically normal condition in these respects of the red cells in chlorosis, should render a diagnosis comparatively easy.

Before considering the disease next to be mentioned it may be well to define a term or two and to refer to the differential staining of blood cells.

Diagnoses of disease are now being made based upon the presence or absence of leucocytosis, and in using this term I shall abide by the definition of it recently given by Cabot, who says that "leucocytosis is the presence in the blood of an increased number of white cells of the same varieties morphologically as those in normal blood, a plurality and generally an overwhelming plurality being polynuclear."

This is a very important distinction, as evidenced by one of his cases, that of a woman who entered the hospital with a diagnosis of malignant tumor. There was so much pallor that a blood count was made, which disclosed a vast increase in the number of white cells (reaching the proportion of one white cell to thirty-nine red cells). This fact, taken in connection with the size and nature of the tumor, led to a diagnosis of leukæmia. But later a differential count of the blood was made with the triple stain, and at once it was seen that the disease was not leukæmia, as ninety-five per cent. of the white cells were polynuclear.

The use of stains in blood examinations was introduced by Ehrlich in 1878-1879. In his study of the white cells—the leucocytes—he found that the granules contained in them were differently affected by certain coloring matters, and that they had a special affinity for the aniline colors. Further than this, that some forms of leucocytes were stained only by acid aniline colors, while others were stained only by the basic coloring matters.

In accordance with these peculiarities a triple stain containing an acid coloring matter, such as eosin, and a basic one, such as methyl blue, in a fluid, with the acid in excess, is commonly used in staining blood. A popular staining fluid is that known as the Ehrlich-Biondi, which contains acid fuchsin, methyl green, and orange G. This stain colors the nuclei of the white cells green, those of the nucleated red cells nearly black, the red corpuscles themselves a light

orange, the eosinophilic granules red, and the neutrophilic granules a deep violet.

In normal blood these various forms of leucocytes bear a definite relation to each other in number, and this proportion is often much changed in disease; in some complaints the change may be pathognomonic.

It is agreed by all authorities that leukæmia can be diagnosed only by an examination of the blood. But while this has long been an easy matter in advanced cases, it is not easy in the early stages, in which alone we can hope for cures through treatment. The history of the disease is marked with cases of leukæmia which have been mistaken for scrofula, cancer, congenital syphilis with enlarged spleen, kidney disease, ovarian tumors, or malaria.

The difficulty of making a diagnosis from malaria in the early stages is well shown in the following case: Mr. M., aged thirty-one. Twenty-two months before presenting himself he had had a severe chill and remained in bed for four days, but had no fever. He continued weak and sickly up to the time of examination. He was said to have had malaria every spring, but could give no reasons for that diagnosis except the splenic enlargement. At the time of examination he was very weak and pale, and the spleen extended from the diaphragm to the pubis and laterally to beyond the median line. A blood count showed fifty times the normal number of white cells, and 4,000,000 red cells.

Of course the blood count made a diagnosis beyond question, as only in leukæmia is there such an enormous increase of the leucocytes. But in active digestion, pregnancy, the puerperal state, and in young children there is a physiological increase to perhaps double the standard number of 8,000. There is also a very large increase of leucocytes in various septic conditions, and in any one of these conditions a mere count of the white cells would not be sufficient to exclude leukæmia.

But if in a differential count we find, instead of the normal, from 20 to 30 per cent. of lymphocytes, from 60 to 75 per cent. of polynuclear, 6 per cent. of mononuclear, and from 2 to 3 per cent. of eosinophiles, a great decrease of lymphocytes with the presence of enough of a new form, the myelocytes, to replace the deficiency, there is no longer any doubt of the diagnosis.

In pseudo-leukæmia, or Hodgkin's disease, there may be a leucocytosis, which, together with a decrease of red cells, may so closely resemble true leukæmia that only a differential count of the blood cells will decide.

Bremer has recently perfected a method of making a diagnosis in diabetes by blood staining. He uses a mixture of eosin and methylene blue compounded in a very complex manner, and stains the red cells with it. Diabetic or glycosuric blood is stained a sap- or bluish-green, while non-diabetic blood stains a reddish violet. He claims this test to be so delicate that an amount of sugar too small to show in the urine will give the reaction in the blood.

In cases of simple leucocytosis very valuable information may be gained without staining the blood.

Several writers, including a number of German authors, have claimed that leucocytosis is present in all febrile affections with increased activity of the lymph glands, but many microscopical tests by careful observers have shown that this is too sweeping a statement. For instance, while there is at times a leucocytosis in tuberculosis it is only while the tissue destruction is active. In typhoid fever there is no leucocytosis, and this fact is of very great importance in deciding in a doubtful case between typhoid fever and purulent affections such as meningitis, appendicitis, abscess, and general infection.

But in pneumonia there is a marked leucocytosis except in cases that prove fatal, and in doubtful cases in the early stages a blood count would aid in the diagnosis; and in making a diagnosis between it and the grippe, in which there is no leucocytosis, the examination of the blood may be of very great use, especially when depressive drugs are used for the grippe. In gynecological work an examination of the blood should be of use in a few cases in determining whether the symptoms are due to the irregular pelvic neuralgias with which we sometimes meet, or to a beginning pus tube or malignant disease.

In rise of temperature after operation a count of the leucocytes may be of value in determining the presence or absence of pus. In a recent case in which I had removed a carcinomatous breast, the temperature rose to 101° F. after having been at normal, and the question suggested itself whether there was pus or whether the tension of some of the stitches, coupled with the excitability of the patient, was the cause of the high temperature. A blood count showed 19,000 leucocytes, and with the removal of two or three stitches a small amount of pus was discharged, and the temperature fell.

In deciding whether a case is one of appendicitis or some condition such as intestinal obstruction, or even constipation, which sometimes resembles appendicitis, the absence of leucocytosis should make the surgeon hesitate about operating.

The blood parasites offer very valuable diagnostic information. The most important of these yet known is the plasmodium of malaria. When Laveran first announced his discovery of this hematozoön his claims were denied by others who could not find the germ he described. And though its presence is easily demonstrable with a little perseverance, so little interest was taken in the subject that it was several years before its existence was admitted by leading clinicians, and even now there are men of repute who declare that the so-called malarial parasite is found in the blood in all conditions.

But the masterly treatise of Manson is alone sufficient to set this matter at rest; and in addition to that, any one may decide it for himself with a high-power microscope. All that is needed is to put a drop of fresh blood on a clean glass slip and carefully examine it under a $\frac{1}{2}$ inch oil-immersion lens, though it may be seen, if one knows what to look for, with a less powerful lens.

The main difficulty which confronted the earlier observers was the fact that the malarial parasite is not the same in appearance in all stages of the disease. Thus, if we examine the blood in a case of benign malaria, just before the rigor, we find a cluster of bodies in a blood cell arranged so as to resemble somewhat a rosette with a small mass of pigment in its centre. If we again examine it an hour or so after the chill, while the temperature is still rising, we may see a number of small bodies in a blood cell arranged in an irregular circle near its periphery and in active motion. If the examination is repeated several hours later, these actively moving bodies have disappeared, and in their stead are seen larger amœboid bodies, each body being pale but containing one or more grains of a very dark red or intensely black pigment, which if carefully observed is seen to be constantly changing its position. If we once more examine the blood a few hours before the next paroxysm is due, we find that these pale bodies nearly fill the blood cells they occupy and are no longer actively amœboid, and that the granules of pigment are coarser, more numerous, and nearly stationary. The cycle of change is then complete. These forms and changes are slightly different in quartan from those in malignant malaria, and it is quite possible that the germ is not the same.

Some form of the parasite may be seen in every case of true malaria during the activity of the symptoms, though in some mild cases many microscopic fields may have to be examined before detecting it. Although the diagnosis of a case of malaria may generally be made and the appropriate treatment used, other affections, such as hectic fever, deep-seated suppurations, nervous chill, and the chill of catheterization may be mistaken for it, unless the blood is examined.

The last blood parasite I shall consider—that of anthrax—is famous, as being the first germ proven to be the cause of a specific disease.

This disease is rare in this country, but occurs in all sections of it. Nearly every case recovers if properly treated at its inception, while in those of late diagnosis the mortality is as high as sixty per cent.

The bacillus cannot always be found in early cases, but is so large and distinctive (being a straight rod with a length equal to twice or three times the diameter of a red corpuscle) that a diagnosis can at once be made upon seeing it.

In conclusion I would like to call attention to the possibilities there appear to be in this field of study. What has been done thus far is merely a beginning in the field of hæmatological investigation.

There are several diseases in which the blood has not been examined in its clinical aspects and many others in which the work done is as yet so small that no positive opinion can be based upon it.

It will be noticed that most of those diseases in which the results of blood examinations have been most marked are among the members of that group of so-called essential or idiopathic diseases. It may be that through the blood we can not only determine their character but also discover their causes and their cure. Bremer thinks that, while his test for diabetes is effective only in the presence of grape sugar, it is not the sugar alone, or even primarily, that is the essential characteristic in this disease, but that its clinical symptoms are due to some other foreign substance in the blood. The study of blood offers an excellent opportunity to any careful observer, for, although the best results are not mathematically exact, the error is so small that it may be disregarded. But on the other hand, the slightest neglect of details may cause an error of fifty per cent. without the operator's being aware of any mistake.

Infectious Diarrhœa in Infants.—Dr. H. M. McClanahan says: "Stop the food supply. Remove the products of imperfect digestion from the intestinal tract by irrigation, continued until the water returns free from admixture of fecal matter. Inject solution of twenty grains of tannic acid in a pint or more of sterilized water, and have it retained in the bowel about an hour. When vomiting persists the stomach should be washed out also. To neutralize the toxins calomel in one-tenth grain doses hourly for the first twenty-four hours is recommended. First among antipyretics is the cooled bath. When watery discharges continue after the irrigation, hypodermics of one-one-hundredth grain of morphine and one-eight-hundredth grain of atropine can be given. Stimulants are indicated in the severe cases, and whiskey is the best that can be given. After the urgent symptoms have subsided the child can be nourished with the white of an egg stirred in cold water or the mixture recommended by Jacobi: Five ounces of barley water, the white of one egg, one or two teaspoonfuls of brandy or whiskey, some salt and sugar. A teaspoonful every five or ten minutes as indicated. No milk should be given for several days."—*American Journal of Obstetrics and Diseases of Women and Children.*

A MEDICO-LEGAL CONSIDERATION OF SOME OF THE GENERAL FEATURES, SIGNS, AND SYMPTOMS OF THE SIMPLE TRAUMATIC NEUROSES.¹

BY A. L. HALL, M.D.,

FAIR HAVEN, N. Y.

VIEWED from a medico-legal standpoint, there is no more important and interesting subject in neurology than the traumatic neuroses.

Much of the importance which attaches to this subject is due to the frequency with which cases are made the basis of an action for damages for bodily injuries arising from accidents.

It is interesting, chiefly, on account of the complex and varying nature of the symptoms, the absence of special objective signs, and the want of reliable tests for detecting simulation.

For many years the subject received consideration only at the hands of the surgeon, and not until the appearance of Erichsen's treatise upon spinal concussion were the nervous aspects of the disease brought into special prominence. Since then neurologists inspired by the writings of Page have investigated the various nervous phenomena of the affection and as a result of their labors about three hundred articles upon the traumatic neuroses and questions connected therewith have been published.

In consequence of the incorrectness of many of Erichsen's conclusions respecting the pathology of the disease, the ability of the surgeon properly to elucidate its nature is seriously questioned by the neurologists. As an outcome many, if not most, of our surgeons have retired from the field of investigation, leaving the inquiry to the neurological expert, who with his instruments of precision attempts a scientific determination of the signs and symptoms, without sufficient regard, in many instances, for the practical deductions.

The object of adverting to the tendency of the neurologist to usurp the entire field of investigation, to the exclusion of the surgeon, is not to discredit the former, but for the purpose of showing that the surgeon, by reason of his earlier and usually prolonged connection with the case, is in a better position, if he has made a careful study of the remote effects of traumatism, than the neurologist—and as well qualified—to determine correctly its gravity and final outcome. For these reasons, the surgeon should maintain his equality as an authority with the neurologist respecting the sequences of trauma upon the functions and structure of the nervous system.

Definitively considered, the condition known as traumatic neurosis is a state of chronic general nervous depression with or without accompanying hysterical manifestation consequent upon physical or psychical shock. Usually, except that it originates from trauma, it differs symptomatically in no important respect from the ordinary exhibitions and combinations of idiopathic neurasthenia. In ordinary cases the symptom complex is expressed somewhat as follows: There is a loss of nervous tone and the patient suffers from a peculiar train of bodily feelings dependent upon a depressed and irritative condition of all the vital functions. The mental state is one of anxious foreboding, irritability, and distress of mind. The attention, will power, and thought concentration are weakened, and there is a keen dislike, or actual inability, for the assumption of any business responsibilities. The muscular power is lessened, tremor and inco-ordination are present, and the reflexes are exaggerated, while at times there may be paresis or paralysis. The special senses are involved. Anæsthesia, hyperæsthesia, and some of the various forms of par-

æsthesia are usually present. Visual disturbances, such as photophobia, asthenopia, and an enlarged and sluggish state of the pupil, are seldom absent, while at times contracted visual field and the graver defects of vision are observed. The senses of hearing, smell, and taste are perverted, but seldom to the extent of occasioning serious annoyance; while sleeplessness, headache, vertigo, loss of appetite, impaired nutrition, spinal pain, and a host of minor derangements complete the wretched state of the subject.

The great majority of cases of the affection occur between the twentieth and fiftieth years of life and are met with very much oftener in men than in women. Most of the cases seen in this country are of the neurasthenic type, although the hysterical element may be detected in a small proportion of the cases. The average age for hysterical cases is said to be less than that for the neurasthenical. This assertion rests upon no substantial data and is scarcely worthy of acceptance. According to the writings of foreign authorities it has striking national peculiarities. In France the hysterical cases preponderate; in Germany the hypochondriacal; and in England the neurasthenical. It is extremely questionable if these differences in symptoms exist in the degree that has been claimed for these countries. Undoubtedly much of these differences may with greater propriety be ascribed to the methods and personal bearing of the observer. The slowly performed, methodical examination best develops the hypochondriacal side of the disorder, while hysterical or neurasthenical tone may be produced and given undue coloring as the result of the bearings and suggestions of the examiner upon the subject. For the most part, however, the symptom complex is determined by the nature of the injury and the previous state of patient. If the subject had always been a neurotic the disorder would tend to assume the neurasthenical form; if emotional to an unusual degree prior to the accident, the hysterical type of the trouble would probably develop.

Not infrequently is witnessed in our courts the spectacle of a serious contention arising through the disagreement of the experts concerning the precise nature of the neurosis encountered: whether it be hysteria, or neurasthenia, or an intermingling of the symptoms peculiar to these affections. Hysteria may have existed prior to the injury, and proof of its existence would go far toward establishing a successful defence to an action for damages if hysterical expression were the chief or only manifestation exhibited after the injury. Again it might be alleged as a defence that the claimant was a "neurotic" before the injury occurred. If such allegations were sustained by competent evidence compensation would as a matter of justice be lessened or withheld by our courts. Thus it may happen that the particular phase which the neurosis assumes is sometimes of more importance than any other question connected with a given case.

The claim made by some of the leading neurologists of to-day that neurasthenia and hysteria are due to disintegration of the nervous system is plausible enough and possibly may be true: but unfortunately, like too many other claims of modern medicine, it is, in our present state of knowledge and with the means at our command, incapable of satisfactory demonstration. The older theory of dynamical disturbance of the nerve elements as causative of hysteria and neurasthenia is by no means exploded by the newer theory of nerve disintegration. Both theories are tenable, but one is no more proven than the other.

Statistics have been introduced into the current literature of the subject which appear to prove conclusively that the traumatic neuroses are developed with greater frequency and with more intensity at or near the large centres of population, while the converse oc-

¹ Read at a meeting of the Syracuse Academy of Medicine, June 16, 1896.

curs in the remote country districts. Without doubt the affection is oftener seen at populous points, but not to the extent that has been claimed. In country districts such conditions are not so well understood nor so readily recognized by physicians; while, upon the contrary, the physicians of the cities not only recognize these traumatic states but they put their patients by their instructions in a position to realize the importance of the dangers which may remotely result from traumatic influence. Resulting, then, as it may, from a great variety of causes, traumatic neurosis is by no means of infrequent occurrence in country districts, for it is highly improbable that one could fail to find the histories of at least a half-dozen or more well-marked cases in an aggregation of a thousand people anywhere in this country—be it ever so remote from the centres of population. For this reason the affection is a very important one to the country practitioner and he has no just excuse if he does not possess the ability to detect and intelligently treat it.

The question of alcoholic or syphilitic taint may arise and its determination may be an important element in the adjudication of a case. Syphilitic infection is oftentimes set up as a defence, and is usually introduced for its bugbear effect. The syphilitic and alcoholic neuroses are usually not specially difficult of detection; nevertheless, it should not be forgotten that a very profound syphilitic cachexia may manifest itself in a way which may be mistaken for some serious nervous condition, even by very competent observers.

In the consideration of the ultimate effects of trauma upon the nervous structure the physician encounters problems which lie more within the domain of psychology than of medicine proper. The bestowal of compensation upon the industrial classes for slight or imagined injuries has not only its medical aspects for the physician to deal with, but it is a matter of more than passing sociological importance, which, sooner or later, will make itself perniciously felt upon the morals of the people of this country, the same as it has already done in some of the countries of Europe. It behooves, then, the physician who assumes the rôle of the expert to give the most careful consideration to the weight of his utterances respecting the nature and sequence of the trauma which he has to consider. It is no doubt true that if the baneful effects upon the patient of the injudicious suggestions of the friends and attending physician could have been removed from the cases which have been the subject of litigation, more than one-half of the damages heretofore awarded in this country as compensation would never have been bestowed. That many of the symptoms which follow nearly every case of trauma can be accounted for on purely psychological grounds, there is now no dispute. The evils of introspection are in many instances greater than the evils of the suggestions of those having relations with the patient. When these two influences are brought to bear upon a given case, they constitute evils the most powerful and pernicious with which we have to contend in arriving at a correct estimate of the actual damage sustained by the nervous system. As is generally known, it is possible for persons influenced by introspection and suggestion to construct an organized symptom complex identical with the remote symptoms of profound trauma upon the nervous system, and while in this state escape detection and secure a heavy award of money from some luckless individual or corporation without having ever undergone physical or psychical injury. Such simulation is too often witnessed to require the introduction of direct proof of its existence. It may be consciously or unconsciously performed; nevertheless, it is a simulation in its most subtle form. Symptoms so successfully simulated cannot be differentiated

from the symptoms of true cases of traumatic neurosis, except by a history of the case; and in the absence of this knowledge, we have no certain means at our command for the detection of the deception. Use may be made of the various so-called objective signs of the expert neurologist, and instruments of precision without number may be brought into requisition, and, notwithstanding these aids, the acumen and ability of the investigator is unequal to the task of unmasking the imposition, and the case, in the absence of an accurate history, is regarded as genuine. Neurologists, as has been adverted to before, have recently evolved the theory that the traumatic neuroses, in whatever form manifested, are the result of the disintegration of nervous matter. This theory neither sustains nor strengthens the commonly accepted doctrine of the changeable nature of the symptoms of the affection; but, on the contrary, tends to confirm the teaching of those observers who maintain that changeableness of the symptoms indicates exaggeration or simulation. Disintegration of nervous matter is unqualifiedly a definite pathological process and must of necessity give rise to definite symptoms. Changeability of symptoms denotes a converse state of things, or the absence of a fixed pathological condition such as disintegration of the nervous system implies; hence it is evident that the theory of causation is wrong, or else changeableness of the symptoms is either an erroneous conclusion or is due to simulation. Traumatic neurosis, in this country, is usually met with as a neurasthenia. Writers agree that the symptoms of the idiopathic and traumatic varieties of neurasthenia are identical; and the idiopathic form is acknowledged, on their part, to have definite symptoms of sufficient stability to warrant an easy and unfailing diagnosis, while the traumatic type, according to the neurological expert, has changeable symptoms which require special skill and the use of instruments of precision for their determination. It is utterly impossible for any one having a knowledge of the admitted facts pertaining to the forms of neurasthenia under discussion to reconcile conclusions of this character. The disagreement is apparently due to the jealousy of investigators who have originated special tests for the detection of malingering. These tests are intended to establish the presence of objective signs or symptoms which in themselves constitute an unfailing means for obtaining a correct diagnosis in suspected or doubtful cases. Much could be given in the way of description of these signs, but suffice it to say that, as yet, there are no known special signs, alone sufficient, whereby a case of traumatic neurosis can be differentiated from one of ordinary idiopathic neurasthenia. The presence of sprains and other objective evidences of recent injury, together with an authentic history and a stable, well-organized symptom complex, constitute the only reliable factors for differentiating, with certainty, the genuine from the simulated cases of traumatic neurosis. Instruments of precision and special tests are, at times, very valuable aids to diagnosis, but their employment under ordinary circumstances is unnecessary. There are numerous instances in which simulators have successfully maintained their imposture against the tests and armamentarium of the specialist, and oftentimes a little common sense is of more use in diagnosis than all the special tests and diagnostic appliances combined.

"The stumbling-block in the whole matter of the accident neuroses," says a late editorial writer, "lies in the interpretation and significance of the term simulation." According to some observers it is extremely difficult to find many cases of simulation; while, upon the other hand, authorities of equal repute persistently affirm that a large percentage of the number is nothing but wilful, well-disguised cases of simulation.

The controversy over the matter has been long and acrimonious, and has resulted in no special advantage to either side of the question. The discussion, however, has given us the term "simulationists" as a name for those who believe in the existence of a large amount of simulation. The final settlement of the question of simulation will be reached when the matter of the pathology of traumatic neurosis shall rest upon indisputable grounds. If the theory of the disintegration of the nervous system prevails, then stability of the symptoms, whether physical or psychical, will denote genuineness of the affection, and instability of symptom expression will indicate exaggeration or simulation. From what has been said it is evident that the employment of special tests for the determination of doubtful cases has, thus far, failed to give satisfactory results, but, instead, has given rise to an endless discussion, confusion, and disagreement among the experts. Therefore, in view of what we know of the subject, it is evidently always best to stick to the practical methods of examination, even in determining the status of the doubtful cases of traumatic neurosis.

Conclusions:

(1) The surgeon should be an equal authority with the neurologist in determining the sequences of trauma upon the nervous system.

(2) Neurasthenia is the usual form under which traumatic neurosis expresses itself, and its symptoms are indistinguishable from neurasthenia arising from other than traumatic influences.

(3) The actual condition of the patient previous to the accident must be known in order to reach a correct estimate of the damage from injury sustained by the nervous system.

(4) The type of symptoms manifested by the neurosis, whether neurasthenic or hysterical, is oftentimes a question of vital importance in the adjudication of a claim for damages.

(5) Traumatic neurosis occurs oftenest at the centres of population, but it is by no means a rare affection in the country districts.

(6) It is probable that traumatic neurosis is dependent upon some definite—yet unknown—change in the arrangement and structure of the cellular elements of the nervous system, which gives rise to stable rather than unstable symptoms.

(7) A stable, well-organized symptom complex indicates damage to the nervous structures; while instability of symptoms and want of orderly arrangement denotes trivial injury—and, if long continued, simulation is rendered probable.

(8) The so-called "objective symptoms" depend upon the psychical rather than the physical state of the subject, and are unreliable guides to diagnosis.

(9) A correct diagnosis is best obtained from a reliable account of the accident, the history of the previous state of the patient, the presence of surgical troubles and the existence of a stable, well-defined, organized symptom complex.

(10) The term "traumatic neurosis" is an expression for an indefinite condition, and a simplification of the subject is desirable from a clinical standpoint.

Scabies.—Dr. Hare, in *Medical World*, says: "The 'itch' (scabies) is often hard to treat successfully. Sulphur ointment well rubbed in will often allay, but frequently fails of curing because of the depth of the furrows made by the female acarus. It is therefore best, before the application of the ointment, to give the patient a thorough hot bath, lasting half an hour, with strongly alkaline soap, in order to soften the epidermis and uncover the burrow of the worm. The ointment may then be used with much benefit."

THE SURGERY OF EMPYEMA.¹

By T. N. RAFFERTY, M.D.,

ROBINSON, ILL.

THE fact that empyema was not only recognized but treated surgically in the remotest days of antiquity adds interest to the discussions of the present day as to the best surgical procedures for its relief. The surgical treatment of the disease is said to owe its origin to the mythological legend which tells us that Jason, seeking death in the midst of battle, received a spear wound in the chest and was thus artificially relieved of an empyema. The same story, with a different hero, is related by Plinius in the seventh book of his "History of Nature." We also have the oft-quoted case of Kinesiros, whose pleura is said to have been opened by the actual cautery by Euryphon of Knidos. Traced, as it can be certainly, from Hippocrates down through this long series of years, the surgical relief of empyema has afforded a theme for animated discussion as to the proper indications for its performance. Hippocrates² operated by incision with the knife, by actual cautery, and by perforation of the ribs; and operations of this sort seem to have been common enough in his day. Another striking fact is that Hippocrates taught and practised frequent washing of these patients before the operation, and thus really practised what is now known as aseptic surgery. From soon after the days of Hippocrates there is no further account of surgical treatment of empyema for more than two thousand years, when it was revived by Sedillot, but was not looked on with favor by other surgeons, and even Dupuytren said he would rather die of the disease than be killed by the doctors. Since the revival of the operation by Sedillot, however, it has never again been remanded into obscurity, but has gradually come to be considered, in some of its forms, indicated in all cases of empyema that threaten life and cannot be cured by other means. Up to 1850, however, there was no real certainty or agreement as to its use, except as a last resort. About this time Trousseau laid down the proposition that in pleuritic effusions, no matter what their character, we ought not to wait till death is imminent, but operate with the view of warding off dangerous attacks of dyspnoea, which may unexpectedly seize the patient and carry him off with great rapidity. The great Frenchman encountered opposition to his views from every side, notwithstanding his successful results; and the operation would perhaps again have fallen back to its former limited sphere had not Dr. Bowditch, of Boston, begun his brilliant advocacy of Trousseau's doctrine, which was soon aided by the invention by Dr. Wyman, another American, of his suction instrument, and aspiration made possible. Dr. Bowditch operated for empyema two hundred and fifty times, and published papers on the subject in the *American Journal of the Medical Sciences*, April, 1852; *The Medical Monthly*, January, 1853; *Boston Medical and Surgical Journal*, May, 1857; and read his last paper on the subject before the New York Academy of Medicine in 1870. Leaving out the treatment with drugs and counter-irritants, by which it is hoped to produce absorption of the pleural effusion, the lines of treatment now advocated are about as follows: 1st, simple aspiration; 2d, aspiration followed by irrigation with antiseptic solutions; 3d, aspiration followed by permanent drainage, Beulau's method; 4th, simple incision; 5th, resection of small portion of a rib to insure free drainage; 6th, resection of larger portions of ribs sufficient to secure drainage and produce retraction of

¹ Read before the Æsculapian Society of the Wabash Valley, at Terre Haute, Ind., June 4, 1896.

² "De Morbis," Hippocrates.

chest wall, Estlander's operation; 7th, thoracoplasty, or removal of the chest wall, Schede's operation.

Dr. Carl Beck, who is a strong advocate of the resection of one or more ribs in the treatment of all operative cases of empyema, regards it as deplorable that there should be any difference of opinion in regard to the advisability of this method in preference to any and all others. His sarcastic assertion, that an explanation of this deplorable difference of opinion is only to be found in the fact that the "general practitioner" has had the effrontery to attempt the solution of surgical problems, certainly has no scientific weight in deciding the best method of treating a condition that varies so much in different cases as does pyothorax.

Many cases of empyema occur in children, and, for reasons which we shall see later on, it is quite probable they may do well with a less radical treatment than is required in adult cases. So the chronicity of cases, the condition of the lung, and the viscosity of the pus contained in the cavity are all factors that should be considered in deciding whether aspiration, incision, or resection of ribs will be best suited to any particular case. It has been suggested by Dr. Tiffany,¹ of Baltimore, that much depends on the character of the pus found in these cases, not only as regards prognosis, but in deciding the character of the operation required. He advises the use of the hypodermatic needle for withdrawing a sufficient amount of the pus for bacteriological examination, and believes that if the patient has pyæmic cocci he will die under any form of treatment; while if there are only staphylococci, or pneumococci, removal only is necessary without irrigation; but if streptococci are found, resection and washing out are necessary. Cases due to simple infection by pneumococci or staphylococci are therefore to be regarded as benign; those caused by saprophytes, in which case the infection is putrid, as in the highest degree unfavorable; while those arising from streptococcus infection occupy a middle ground as regards their danger to life.² However, in many pleuritic effusions, both serous and purulent, no microbes³ can be found. It has been assumed that such cases are tuberculous, but there seems no sufficient reason for such conclusion. If the empyema is due to a mixed infection, the gravity of the case depends on the predominance of the more virulent bacteria present in the exudate. The very fact that surgeons still differ as to plans of treatment, and show equally good results from their favorite methods, is a striking proof that all cases should not be treated alike. Any effort to inculcate a different doctrine, for the gratification of personal pride in one's own particular method, savors of an egotism that is dogmatic and unscientific.

All operative measures in the treatment of empyema have for their chief end two objects: first, to evacuate the pus or other fluid contained in the cavity; and second, the obliteration of the cavity by bringing together its walls. The latter is best done by that method which closes the cavity by expansion of the lung and not by retraction of the bony thorax.

The first question to be decided in any case is whether any operation is necessary for its relief. This question was discussed in a paper by Dr. John Ashhurst, Jr., of Philadelphia, read at the meeting of the American Surgical Association in 1894. He then said: "No operation is justifiable unless the presence of pus is certain; unless thorough treatment by medicinal agents, blisters, etc., has failed; or unless the dyspnoea and other symptoms are so urgent as to demand immediate relief." Since the presence of pus is never absolutely certain, it follows that we should

not, in ordinary cases, operate unless the symptoms are urgent. If operation is decided on, a simple aspiration should be done unless it seems certain that this will not be sufficient. The aspiration should be done under strictest antiseptic precautions, and with the same care in this regard as though it were a major operation, because on our care in so doing depends the certainty almost of changing a serous effusion, if such is found, into a purulent one.

The point usually selected for aspiration is the sixth intercostal space, but the exact location is largely a matter of choice of the operator. It should be low enough to permit of the emptying of the cavity, and high enough to be out of the way of the diaphragm, which moves upward as the fluid flows out. If the fluid evacuated is serous, and thorough asepsis has been secured, the chances are favorable that nothing more will be required. Following this first aspiration irrigation with antiseptic solutions should not be done. If the fluid is purulent, a reaccumulation is likely to occur, in which case either simple incision or puncture and permanent drainage (Beulau's method) should be practised. These methods favor the obliteration of the cavity by expansion of the lung, and if this takes place the patient is left in much better condition than when retraction of chest wall occurs. If from any cause sufficient drainage cannot be had by either of these methods, then a small portion of rib (an inch is ample) may be excised. If, however, the lung is bound down by adhesions so that expansion is impossible, then the operation of Estlander is certainly indicated, in which case there must be sufficient excision of ribs that by collapse of the bony thorax the costal pleura will be brought in contact with the layers next the lung.

A good many writers on this subject seem to have confounded simple resection of a small portion of one rib, for the purpose of securing and maintaining better drainage than can be had by simple incision, with the operation known as Estlander's, which has for its object an entirely different purpose. The Estlander operation, as before stated, aims at retraction of the chest wall in cases in which the already crippled lung cannot expand, and consists in the removal of extensive sections of two or more ribs. In many cases, however, it has been demonstrated that the mechanism of the cure of empyema is not dependent upon the retraction of the chest walls, and hence a resort to the Estlander operation is not necessary in all cases, even of protracted and extensive pyothorax. Such at least was the report of the committee appointed by the Belgian Academy of Medicine,¹ who, with M. Deroubaix as their chairman, made exhaustive study of the surgery of empyema. Their report, however, retains the Estlander operation in the list of legitimate surgical practice, and leaves the selection or rejection of this operation to the tact and judgment of the surgeon in each particular case. Verebélyi, of Vienna, thinks resection of ribs² is generally unnecessary, and is only indicated when by approximation of the ribs a free exit of pus is hindered. Moullin³ favors a trial of aspiration, and states that in children it is often successful and in case of adults is always worth the attempt. If this is not successful he advises incision and the insertion of as large a drainage tube as the space between the ribs will permit. He resorts to resection only in extreme cases, when there is such an overlapping of ribs that drainage through a tube cannot be accomplished; and regards washing out the cavity with antiseptics as unnecessary and dangerous. Resection certainly increases the liability to pyæmia and produces deformity of the chest. Another and most serious objection to it is that its performance

¹ Transactions American Surgical Society, 1894.

² "American Text-Book of Medicine," p. 522.

³ Koplik: "American Text-Book of Diseases of Children."

¹ Sajous' Annual.

² Treatise in Surgery, p. 836.

necessitates the use of anæsthetics, which not only are not well borne, but are absolutely dangerous in these cases. To operate without an anæsthetic is brutal in the extreme, and only the direst necessity should ever be a sufficient reason for its undertaking. Notwithstanding these and other objections to an operation which is certainly not devoid of danger, it is the plan advocated by many eminent surgeons, among whom may be mentioned Koenig, Schede, Weir, Bull, McBurney, and Beck. Dr. Achutz, in a paper on "The Treatment of Empyema in Children," read before a meeting of the Medical Society of Hamburg recently, emphasized the necessity of costal resection in all of these cases, and reports eighteen operations and sixteen recoveries. He deprecates all forms of expectant treatment and performs the radical operation as soon as the diagnosis is made that effusion exists.

As showing how favorable results are sometimes secured, under unfavorable circumstances and from methods of treatment that would not be considered good surgery by the extreme advocates of resection in all cases of empyema, the following report of two cases is offered. These cases are not reported as embodying all the writer's experience with empyema, nor for the purpose of "deducing classical rules from the results and observation of two cases," but for the reasons above stated.

CASE I.—E. T—, eight-year-old girl, was seen ten years ago in consultation. There was a large effusion in the left pleural cavity, following an attack of pleuropneumonia. The heart was displaced, and its apex beat was to the right of the sternum. The symptoms were urgent and the dyspnoea was extreme. With no antiseptic precautions, the fluid, which was sero-purulent, was aspirated—at least enough of it to relieve the urgent symptoms. The point of puncture was covered with adhesive plaster, which was pushed off very soon afterward by the escape of fluid. This discharge continued for about five months, gradually diminishing, finally ceased altogether, and the fistula closed. The child recovered her health permanently and perfectly, and is now a robust, red-faced young lady, with no chest deformity whatever.

CASE II.—J. R—, aged forty-eight years, has had chronic tuberculosis for years. In December, 1893, he became much worse and was confined to his bed for the next four months. With the advent of warm weather he rallied and seemed much better. At this time no effusion was discovered. Three or four months later he came to my office, and on examination a large effusion in the right pleural cavity was diagnosed. The next day, under antiseptic precautions, sixty ounces of pus were removed by aspiration, much to his relief. At this time, more than a year and a half afterward, there has been no reaccumulation, the tuberculous process has been latent or nearly so, and he has been in very fair condition.

A study of recent literature and observations made at a number of the largest clinics of this country, both east and west, have led me to question the propriety of the extensive resection of ribs in any but the most desperate cases. And while there are, no doubt, many cases in which the resection of a portion of a rib gives better results than the simpler methods, there have been many cases thus operated more for the sake of doing the major operation than with the belief that it was necessary. Especially is this true of the operation of Estlander and the thoracoplasty of Schede. As for other novel procedures occasionally advocated, such as curetting the pleural cavity, etc., they need only to be mentioned to be condemned.

So, too, the indiscriminate use of antiseptic injections is to be strongly deprecated. Many fatal results are recorded as immediately following this practice; and in the operation for ordinary empyema it is

an unnecessary and dangerous procedure. If done at all it should be at later periods, and then the utmost caution should be observed. Surgeons should have "*Non nocere*" for their motto more often than they do, and not allow the *furor operandi* to drive it from their memory. Many, very many, cases of pleuritic effusion do well without any operation whatever, and when operation is necessary the simplest one that will cure the patient is the best.

SOME NOTES ON THE BACTERIOLOGY OF MUMPS.

By P. M. MECRAY, M.D.,

CAMDEN, N. J.,

AND

J. J. WALSH, A.M., M.D.,

PHILADELPHIA, PA.

AN epidemic of mumps in the Camden Home for Friendless Children, in the service of Dr. Mecray, suggested the idea of looking for the cause of the disease in the secretion from the parotid as found in Steno's duct before its entrance into the mouth. The study itself was too incomplete to make the conclusions from it very definitely satisfactory, and the notes are published with the idea that, as we are not in a position to go on with the work, they may prove suggestive to others working in the same line. There is not very much in the literature as to the bacteriology of mumps. The text-books almost without exception ignore it entirely. Much of our work had been done before we found in the periodicals anything very definite or materially suggestive.

The "American Text-Book of Diseases of Children" refers to the investigations of Capitan and Charrin, but does not say where an account of them may be found. We suppose the reference is to their report to the Society of Biology in 1881.¹ This work was done before Koch's classical papers, practically laying the solid foundation of the modern science of bacteriology, had been published, and it is almost necessarily meagre, indefinite, and unsatisfactory. A number of microbes, spherical and bacillary, are described as occurring in the blood and saliva. The flora of the mouth was very little known at that time, and the precautions necessary to prevent contamination from the skin, in making cultures from the blood, were not well understood, so that the findings have not much of scientific value. The conclusion suggested by the research, however, seemed to be that a form of bacillus was concerned in the etiology of mumps.

Previous studies are apt to have an influence in the conclusions of after-observers, and so Bouchard² and Boisnet,³ in isolated cases, and Bordas⁴ in a series of cases found in the blood and saliva bacilli that they considered the cause of the disease.

Considerable study has been devoted to the micro-organism found in parotitis in which the inflammation had gone on to suppuration, but in these cases there had been a mixed infection and pus cocci were of course demonstrable. The infrequency of abscess complicating parotitis makes it extremely unlikely that the mumps organism of itself would ever cause suppuration.

Micrococci distinct from pus cocci were found in the blood and saliva in a severe case of mumps in 1885 by Dr. Netter at La Pitié,⁵ and a coccus that they

thought specific was found by Laveran and Catrin in an epidemic of mumps that occurred among some regiments quartered in Paris in 1893. In their report to the Society of Biology, January 28, 1893, they describe the organism as a micrococcus seen most frequently in the form of a diplococcus, though sometimes found in fours, or as zoöglæa. They grow well on the ordinary media, though rather slowly, clouding bouillon somewhat in twenty-four hours, and appearing on gelatin after forty-eight hours as small white punctiform colonies, which develop very slowly and liquefy some considerable time after coalescence. They grow on potato and give a whitish appearance not easy to detect.

In a further communication to the society, May 20, 1893, they report that they had found the organism in sixty-seven out of ninety-two cases of mumps examined. In the exudate of the inflamed gland obtained by puncture with a syringe, they found it thirty-nine times out of fifty-six in pure culture and twice in mixed cultures. The fifteen negative results they consider due to the fact that but an extremely small quantity of the exudate could be obtained. In the exudate from the metastatic orchitis of mumps the organism was found in twelve out of sixteen cases, in pure cultures. The blood of patients gave pure cultures of their "diplococcus" ten times in fifteen trials when taken during the fever. In all cases growths of the micro-organism had to be obtained, as it could not be found in the blood or secretions by the microscope directly, the number of cocci present seemingly being very small.

This micrococcus form, usually seen as a diplococcus, was the principal feature of our findings in cultures from Steno's duct made during the height of the disease, and we had isolated and noted its mode of growth on various media before we knew of Laveran and Catrin's work. The method was as follows: The mouth was thoroughly washed out with a saturated solution of boric acid, and the orifice of the duct, after some slight massage of the cheek to empty it, was covered by a swab of cotton soaked in the solution, and this was allowed to remain between the jaw and cheek for five minutes. A bit of sterile silkworm gut was then introduced into the duct and from it an agar slant was inoculated.

Out of ten tubes six had a mixed growth, but in all of them there was noted a small, white, slow-growing colony. This was isolated in plate cultures and was found to contain two different organisms, one a streptococcus form, the other a micrococcus, nearly always seen as a diplococcus. Further culture showed that the streptococcus grew more rapidly and liquefied gelatin sooner (in three to five days) than the micrococcus. It did not occur in the original cultures as constantly as the latter, the diplococcus form, occurring for certain in eight of the ten tubes and being considered to be present in the others, though this could not be demonstrated with certainty, owing to invasion of the colonies by the more rapidly growing cocci so common in the mouth, which our precautions had not succeeded in entirely eliminating.

We had been studying only the cultures from the duct, but, as Laveran and Catrin had reported the presence of the organism in the blood, we made cultures from the blood in eight cases. The blood was drawn from the lobe of the ear, and to avoid contamination by micro-organisms from the skin thorough cleansing was employed. The part was washed with soap and water, then with alcohol, then with 1 to 500 bichloride, then with alcohol again, which was allowed to evaporate; puncture was made with a sterile needle, the ear being supported by a sterile towel (all these precautions, almost impossible in private practice, were comparatively easy to be carried out in a pub-

lic institution). Out of the eight tubes two gave an entirely negative result, three gave pure cultures of the characteristic diplococcus, and three gave a mixed result, the diplococci being found, but with them other cocci, notably a staphylococcus form, probably the staphylococcus epidermidis albus.

Control tests made from the blood of five healthy children gave absolutely negative results. Cultures made from Steno's duct in these same children gave us various oral micro-organisms in four cases, but not the diplococcus found in the mumps cases.

Beyond this our observations did not go. Though a single case¹ has been reported in which a dog playing with a child that had mumps suffered from swelling of the parotids, malaise, etc., this must have been a coincidence, or a number of cases would have been reported, as domestic animals are so often exposed to the contagion and yet do not acquire it. Laveran and Catrin found that the injection into the testicle of pure cultures of the micrococcus isolated by them set up orchitis, but, as almost any irritant would do this in tissues so susceptible and highly organized, the observation does not seem of much scientific value.

Micrococci of various kinds are so common about the mouth and so easily contaminate cultures made from the blood, that the suggestion of such a form as the specific bacterial cause for one of the infectious fevers is usually set down as due to insufficient precautions in avoiding contamination while making the cultures. The characteristics of the growth of the micrococcus described are sufficiently like those of that very common organism, the staphylococcus epidermidis albus (Welch) to greatly strengthen the impression that perhaps this or some degenerate form of the ordinary cutaneous and oral micrococci is here described.

The diplococcus we found, however, seemed to grow even more slowly and to liquefy gelatin after a considerably longer time than the staphylococcus described by Welch. The negative results in the cases of healthy children living under just the same circumstances, and on whom the same precautions were employed, would seem to show that it was not an organism ordinarily present.

What etiological connection it may have in the absence of the possibility of producing the disease in animals it is hard to say, but there is certainly to be found pretty constantly in the blood and parotid secretion of mumps cases this diplococcus which is not found in children unaffected by the disease.

As a number of forms of cocci are known to invade the parotid gland and set up a non-specific parotitis in systemic septic conditions or during states of lowered vitality, it does not seem so improbable as it might on first thought that the specific cause of infectious parotitis is a form of coccus.

The micrococcus isolated by us grows in pairs, occasionally in fours, rarely in larger groups. Each individual coccus is very regularly rounded, and about the size of the ordinary pus coccus. The colonies are small, white, glistening, distinctly defined, regularly circular spots, at first discrete and of very slow growth, gradually coalescing. The slow growth is a marked characteristic. In making pure cultures three days after inoculation gelatin tubes were set aside as failures, no growth being noted; three days later the small white colonies were distinctly visible. At ordinary temperatures gelatin does not begin to liquefy for from ten to twelve days and liquefaction proceeds slowly. A faint white streak appears on the third day on potato and slowly spreads as a delicate whitish film. On blood serum growth is more rapid than on other media, and the colony is not so distinctly white in color.

¹ Whittaker: "Mumps," Pepper's "Text-Book."

Litmus milk changes to pink on the third day and coagulation takes place. Milk seems an excellent nutrient medium for it and a ready means of spreading contagion.

NOTES UPON THE ESTIMATION OF THE NUMBER OF BACTERIA IN MILK.¹

By MAUD J. FRYE, M.D.,

BUFFALO,

CLINICAL INSTRUCTOR IN DISEASES OF CHILDREN, UNIVERSITY OF BUFFALO;
VISITING PHYSICIAN TO THE ERIE COUNTY HOSPITAL, CHILDREN'S WARD.

THE examinations of milk which this paper reports were undertaken on account of the writer's interest in pædiatrics, the object in doing the work being to learn, so far as such a bacteriological test would teach, the fitness of milk from various sources for infant feeding. The facilities of the pathological laboratory of the University of Buffalo were at the experimenter's disposal, and the work was done under the direction of Dr. Herbert U. Williams.

The method used for counting bacteria in milk was as follows: To a test tube containing a definite quantity of sterile water, say 50 c.c., 0.5 c.c. of milk was added and the contents of the tube thoroughly shaken. One cubic centimetre of this mixture, containing 0.01 c.c. of milk, by means of a sterile pipette was added to a test tube containing liquefied sterile nutrient gelatin or agar. This tube was then whirled or agitated until the gelatin and diluted milk were thoroughly mixed. The contents of the tube were then poured into a sterile Petri plate. These plates, whether gelatin or agar was used, were kept at the room temperature. At the end of forty-eight hours in summer, after seventy-two or more in winter, the colonies were counted. The apparatus used for this was devised in the laboratory. The Petri dish was placed over a piece of glass, the under surface of which was painted black, the upper surface ruled in square centimetres. Then with the aid of a small magnifying glass, which in this case was an ordinary engraver's lens, the colonies were counted. If not many were present the entire surface was gone over; if the number was great, ten alternate squares were counted and the number on the plate estimated from the area of the dish. The number of colonies represented approximately the number of bacteria in 0.01 c.c. of milk. At the time of making the culture two control plates, one of the water used in diluting, one of the medium, were made. So long as these remained sterile whatever grew on the milk plates necessarily had its origin in the milk.

The dilution of milk is necessary for two reasons: First, To add to the gelatin even 0.5 c.c. of milk would make a mixture so opaque that the little grayish or creamy white colonies would be indiscernible. Second, even in the best milk the number of bacteria in 0.5 c.c. is so great that it would be almost impossible to count them. Indeed it is only the best milk that requires so little dilution. At this time of the year (June) for grocery milk a second dilution is done and cultures are made from a mixture of which 1 c.c. contains approximately 0.0001 c.c. of milk. Of course so much dilution increases materially the chance for error.

Gelatin was used as a culture medium until the weather became so warm that it liquefied at the room temperature, when agar was substituted. Either medium has its disadvantages. The rapid development of liquefying organisms in gelatin soon renders counting impossible. No less an objection is the cloudiness which certain bacteria produce in agar. In which medium the greater number of colonies

develop was not determined. One experiment showed about the same number in each.

The influence of temperature on the number of bacteria in milk is noticed in comparing the results of examinations of the same milk supply made last winter and this spring and summer.

A point of some interest is that all bacteria do not develop with equal rapidity. There will be a considerable increase beyond the number found on the usual day of counting.

Certified milk plated February 6th on February 11th showed 88 colonies, on the 13th, 139.

Grocery milk plated March 21st showed on the 23d 246 colonies; on the 24th, 369.

Sterilized milk (from dairy) plated April 2d gave 8 colonies on the 7th, 10 on the 11th. No further increase was found, though the culture was kept one month.

Crèche milk plated May 13th showed on the 16th, 84 colonies; on the 18th, 158.

Certified milk plated May 9th showed on the 12th, 255; on the 14th, 323. The same plated May 16th gave on the 18th, 350; on the 19th, 480. The same in agar June 10th showed on the 12th, 44; on the 13th, 58.

It is well known that milk is a medium in which bacteria multiply with great rapidity. Indeed the enormous numbers found in milk depend probably not so much on the extent of the original contamination as upon the length of time and the conditions under which the milk has been kept. But one experiment illustrating this has been done. Certified milk of that day's milking was brought to the laboratory and directly plated. Two days later the plates showed 57,600 bacteria to the cubic centimetre. The milk was left in laboratory, covered as it is sold, for four hours, the room temperature being from 68° to 72° F. A second plate was then made which at the end of forty-eight hours showed 747,200 per c.c.

The examinations of which records have been kept give the following results:

TABLE I.—MILK AS DELIVERED TO THE CONSUMER.

1. December 28, 1895, bottled milk.....	400,000 to c.c.
2. January 28, 1896, sold by measure....	590,000
3. May 27th, sold by measure.....	24,613,900
4. May 29th (same as No. 3).....	9,820,000 } Many
5. May 30th, brought from dairy.....	9,963,000 } moulds.
6. May 31st, bottled milk.....	796,800
7. June 3d (same as No. 1 and No. 8)....	48,000
8. June 11th (same as No. 1 and No. 7)....	6,630,000
9. June 11th, brought from dairy.....	43,600,000

The conditions under which cultures 3 and 4 were made were not fair, as the milk had stood some time in the laboratory before being plated. They merely illustrate the possibilities of milk as a culture medium. In all other cases the milk, which was brought to the laboratory in sterile bottles, or in the bottles in which it was delivered to the consumer, was immediately plated. The specimens brought from dairies were in both cases got in the afternoon. Morning cultures would show fewer colonies, yet the milk is bought even for little children in the afternoon.

TABLE II.—GROCERY MILK.

1. January 26th.....	25,000 to c.c.
2. March 23d.....	246,000
3. May 25th.....	2,619,900
4. May 26th (culture at 4 P.M.).....	25,090,000 Moulds.
5. June 10th (same as No. 1).....	1,220,000
6. June 11th (culture at 11 A.M.; same as No. 4).....	7,390,000

The milk sold at the grocery which supplied the material for cultures 1 and 5 is received each morning from the country. The first culture was made during extremely cold weather, and probably does not

¹ Read before the Buffalo Academy of Medicine, June 16, 1896.

represent the average condition of that milk in winter. Grocery milk compares very favorably with that from other sources.

Table III. gives the results of examinations of "certified milk." This milk comes from a dairy located some distance out of Buffalo, the manager of which endeavors to supply clean and wholesome milk. The stables are kept scrupulously clean; the cows, all of which have been submitted to the tuberculin test, are daily groomed; the food and water supply of the cattle receive careful attention; the milkers are required to be clean, and the pails, bottles, etc., are bacteriologically clean. The milk is shipped and delivered packed in ice. The name "certified" is given to the milk from the fact that a committee of physicians certify to their knowledge of its condition, a bacteriological examination being made semi-monthly by Dr. Herbert M. Hill to determine how nearly clean the milk is kept.

TABLE III.—CERTIFIED MILK.

1. January 20th.....	13,000 to c.c.
2. February 11th.....	10,000
3. May 12th.....	25,900
4. May 18th.....	35,000
5. June 2d.....	132,720
6. June 10th.....	4,400
7. June 15th.....	57,600

A culture made by Dr. Hill of the same milk on May 18th, a different medium being used, gave 26,000, which we regard as a confirmation of our results.

Table IV. is milk prepared for the infants received at the Fitch Crèche, a day nursery for the children of working women. Milk sent from the country on the morning of the day it is used is sterilized in the Arnold sterilizer, being kept at the boiling point for forty-five minutes. The cream used is prepared in the same way. The bottles containing milk and cream are stoppered with absorbent cotton, cooled, and put into the ice chest. Boiled water is kept in a fruit can in the ice chest. The lime water used is made at the crèche, with boiling water. The milk sugar is dissolved fresh in boiling water each time. These ingredients are mixed for each feeding as needed. The bottles are filled after using with cold water, then as soon as possible scalded and filled and left to stand with a solution of borax. All dishes used in making up the mixture are kept for this purpose alone, and are well scalded after use. That the preparing of the food is carefully done I am confident. Yet examinations of the mixture give the following results:

TABLE IV.—CRÈCHE STANDARD MIXTURE.

1. May 16th.....	8,400 to c.c.
2. May 29th.....	17,600
3. June 1st.....	456,320
4. June 12th.....	31,000
5. June 13th.....	851,440
6. June 15th.....	1,002,400

The fault in this process is that the bottles have to be opened repeatedly, giving chance for contamination. But the bacteria in this mixture, really only a relatively small number, seem harmless. At any rate the babies thrive on it.

Some points which may be noted are these:

Certified milk contains comparatively few liquefying organisms, cultures occasionally showing none at

all. The hay bacillus and the potato bacillus, both liquefying organisms common to milk, and both by some accused of an active part in certain digestive troubles of infancy, may be said to be present in this milk in small numbers if at all.

No count is anything more than approximately correct. All estimates probably fall far short of the actual number of bacteria present.

Counts, to be of value in comparing the purity of various kinds of milk, must be made under identical conditions as regards medium, temperature of room, and time of counting.

This work was begun with but little faith in its value, but as it went on the conviction grew that by ascertaining the number of bacteria in a given quantity of milk we had a valuable test as to its fitness for food; the original amount of contamination, the length of time the milk has been kept, and the conditions of temperature and cleanliness determining the luxuriance of bacterial growth.

PATHOLOGICAL LABORATORY, UNIVERSITY OF BUFFALO.

A CASE OF INFECTIOUS ENDOCARDITIS.

By EDWIN GLADMON, PHAR.D., M.D.,

WASHINGTON, D. C.,

MEMBER OF THE MEDICAL ASSOCIATION OF THE DISTRICT OF COLUMBIA AND OF THE AMERICAN MEDICAL ASSOCIATION.

G. A. F—, male, white, American, aged forty-five years; neurotic temperament; occupation, bookbinder; temperate habits. Father and one uncle died suddenly with heart disease; the mother's death due probably to phthisis. There was a history of so-called bilious attacks for the past ten years, one or two of which confined him to bed for three months.

He first came under the writer's care about five years ago during one of these attacks. They were ushered in,

CHART 1.—Temperature from November 2 to November 8, 1895. Four observations daily.

as a rule, without warning. Sudden vertigo was followed by immediate vomiting, with violent pain either centring solely in the umbilical region or radiating from there to the liver; constipation was always present, though never in a marked degree; there was slight fever, with full, rapid pulse for a few days. Vomiting was always incessant, and enormous quantities of wind would be belched for several days. He was usually confined to bed for a week or ten days. The attacks occurred at intervals of about six months, until February, 1894, the date of the last until the beginning of his final sickness, July 25, 1895.

He had been granted leave from office and was ready to leave the city the following day. His two boys had been sent on to Connecticut by themselves. Coming back from the depot, he seemed much worried about the risk he ran in sending the children on alone. In this nervous condition he sat down to

room, and in a lesser degree could be noticed in both iliac arteries.

The next three weeks no improvement whatever was noted. The epigastric pain increased, and while there was no nausea, vomiting occurred spontaneously every three or four days after taking food. Gastric carcinoma was suspected, though the acid test was not made.

August 22d he went to Boston by steamer, but missed the boat coming home, and was thrown into a crowd of returning excursionists, becoming very much exhausted. He was taken to the seashore, and, his pain increasing and his general condition showing no improvement, he was brought back to Washington, September 4th. No fever was noted before he went, though temperature was not taken. On his return, fever of an irregular type came on, and in about two weeks Dr. S. S. Adams was called in consultation. He was then more or less hysterical, having frequent crying-spells

CHART 2.—Temperature from November 9 to November 18, 1895. Four observations daily.

luncheon, and was at once taken with what seemed to be one of his "old spells." The colon was irrigated (he had since his last attack been using a colon tube); bismuth, lactopeptin, carbolic acid, and hot solutions of phosphate of soda were given, with seemingly good results. The acute symptoms subsided much sooner than in his previous attacks, and the difference between the two then became noticeable.

First was noted a marked intermittence in the heart's action. Strychnine was given with good results, and when he left the city three weeks later his pulse was full and regular. The next difference noted was pain at the epigastrium, radiating to the back. This became so violent as to prevent sleep and required morphine for its relief. It was not influenced by eating or drinking. This was followed or rather accompanied by an utter and complete physical prostration. His appetite was fair and the food of a nourishing character, but his decline in strength was continuous. Epigastric pulsation was visible across the

and an idea that something was growing in him. Rectal nutrient enemata were given, with brandy and large doses of bromide of potassium. Nothing was given by mouth. The epigastric pain disappeared, vomiting ceased, and he seemed to improve. Murmur, most intense at apex, was detected.

In about a week, October 1st, a severe rigor was followed by high fever and profuse sweating. Fever seemed of a quartan type, and he was given quinine, dialyzed iron, and arsenic. This irregular fever continued about three weeks.

From October 21st to November 2d fever ranged from 97.6° to 99.5° F.

November 2d, 6 P.M., severe rigor; temperature, 107° F., followed in a few hours by a fall to 98° F.

From that time to the day of death (about one month), with the exception of two or three days, fever was never absent. It was of hectic type, two, three, or more exacerbations daily, accompanied irregularly by chills and sweats. There was bronchial catarrh during

CHART 3.—Temperature from November 19 to November 28, 1895. Four observations daily.

CHART 4.—Temperature from November 29 to December 6, 1895. Four observations daily.

the last month. The sputa and urine were repeatedly examined by Dr. George N. Acker, with negative results. Abscess of liver was suspected, from its enlargement. Dr. W. W. Johnston, who had also been called in consultation, aspirated the liver, with no result. Aortic murmur was very loud.

From about October 1st to death, petechiæ appeared on different parts of the body, principally on the hands and feet. These were preceded by a circumscribed redness, about two inches by three, on the inner side of the right thigh, accompanied by intense burning and itching. Several joints became affected. First the hip, simulating sciatica; then the right wrist, left shoulder, left wrist, and left foot. Just before death, the right foot seemed to be the only joint affected, and was much swollen and very painful. Pain was occasionally complained of in the left loin and over the right lobe of the liver. A swelling of the size of a large walnut appeared on the left frontal bone, and was painful. The latter part of his illness was characterized by a phthisical buoyancy of mind, as contrasted with the hysterical morbidness of the first part. His meals, as a rule, were eaten at a table to within a week of death, and he rarely spent a whole day in bed.

Five days before death pulmonary œdema of both lungs ensued and was followed by collapse. Recovery under heart stimulants and ammonium iodide and chloride was slow. Ascites then developed, but lessened considerably before death. There was amnesic aphasia for five days before death, with more or less delirium. Flapping in and out of both cheeks was noticed, but it was not persistent. There was retention of urine during the last two days and several times previously.

Notes of autopsy by Dr. J. R. Wellington: E. A. F.—, white, aged forty-five. Three hours after death: No rigor mortis; considerably emaciated. Pericardial fluid increased in amount; the heart, particularly the left ventricle, very much enlarged. The arch of the aorta dilated and infiltrated with calcareous deposits. Endocardium not examined. Lungs emphysematous around edges, otherwise normal. Liver larger than normal, extending to within two inches of umbilicus; very friable, light in color, showing signs of apparently fatty degeneration. Spleen slightly larger than normal, and on being incised was found to contain two abscess cavities of about the size of a walnut, with a dirty brown pus. Stomach distended; intestines normal. Kidneys each showed large infarctions of long standing. Brain not examined.

Report of examination of heart, spleen, and kidneys, by Dr. D. S. Lamb, pathologist to the Army Medical Museum, Washington, D. C.

"Heart shows hypertrophy and dilatation of left side (left auriculo-ventricular orifice stuffed with cotton). Edge of anterior leaflet of mitral valve much thickened, and is capped with a large irregular mass of fibrin, which was removed in handling and now lies loose. Left ventricle contained washed and dark clots, which have been removed. Leaflets of aortic valve are irregularly thickened and edges nodulated; right leaflet shows atheromatous abscess perforating into myocardium and into ventricle, and also a large vegetation. Both valves are stenosed and incompetent. Aorta and innominate artery are much thickened, and show fibrous and calcareous atheroma. Coronary arteries are rigid with calcareous deposit.

"Spleen, coronally bisected, shows one large solid and two softened infarctions.

"Kidneys show large infarctions."

Dr. Walter Reed, U. S. A., says that he found diplococcus lanceolatus in the vegetation of the heart valves. On inoculating an animal, however, there was no pathogenic result, perhaps because the virulency had diminished or ended.

COUNTER-IRRITATION IN THE TREATMENT OF HERPES.

By THEODORE WILKINS, M.D.,

POMONA, CAL.

A NUMBER of years ago I came across an article in some medical journal—I think, the *MEDICAL RECORD*—to the effect that some man, whose name I have forgotten, had treated herpes zoster by applying a fly blister over the affected nerve trunk posteriorly, in every case aborting the attack.

The treatment seemed so simple and withal so rational that it commended itself to my mind, and since then on various occasions I have treated herpes by counter-irritation, with the happiest results. Under these circumstances it seems to me this method of treatment should not be forgotten; for that reason I report the following cases.

Herpes is now generally recognized as a disease of the nerves, producing trophic changes in the skin. As a rule, it lasts for several weeks, and is often very painful. If counter-irritation will restore the integrity of the affected nerve or enable it to hold its own against possible bacterial infection, it is certainly a useful measure which ought to be known and practised early in all cases of herpes.

In all or nearly all cases of herpes search will reveal a tender spot higher up over the nerve trunk. This was found in all but one of my cases, and over this the blister was always applied. In that case, Case I., there was a curious anomaly—herpes in the terminal branches of the sciatic nerve was accompanied by a tender spot in the anterior crural, and promptly cured by a blister there applied. I do not pretend to explain this—I merely present the facts.

CASE I.—Mrs. B.—, a stout lady, forty-six years of age, came with a well-marked herpetic eruption over the upper contiguous edges and surfaces of the great and second toes of the right foot, which had troubled her for some days, causing great pain. It corresponded to the distribution of one of the distal branches of the great sciatic nerve. A very tender spot was found in the course of the anterior crural nerve, in the region of the saphenous opening, and here a blister the size of a half-dollar was applied. The pain in the toes soon ceased, and the eruption dried up within twenty-four hours. There was no other medication of any kind.

CASE II.—Mr. C. B. O.—, an elderly gentleman of stout habit, but very temperate in all things and a total abstainer. This was a case of herpes zoster which I considered intercostal neuralgia until the characteristic eruption began to appear. This was first recognized by his wife, who had herself had "shingles," and she came in great distress to tell me of her discovery. Blisters were applied posteriorly over the sensitive nerve trunks, with cure in twenty-four hours, to the great delight of himself and wife.

CASE III.—Mrs. H.—, a middle-aged, fairly healthy woman, who had been under a great nervous strain, associated with deep sorrow, for many months. One day she showed me a "sore" which had troubled her for some time. It was a well-marked herpetic lesion, situated about two inches below the knee on the anterior inner aspect of the leg. A few inches above the knee, in the course of the anterior tibial nerve, was a very tender spot. A small fly blister over this cured the lower sore promptly.

The next two cases, almost exactly similar in all particulars except the final result, and occurring within a short time of each other, seemed made for a "control experiment," and as such one of them unfortunately served. They both occurred in young women of the same general type—tall, slender, delicate, neurotic society ladies.

CASE IV.—Miss B. C.— had suffered just before from a mild parotitis of the right side, probably mumps. She came complaining of a very sensitive lump, about the size of a hazelnut, in front of the right ear; another, smaller but equally sensitive, was situated lower down in the neck. In addition, there were three soft, red, burning, painful swellings on the forehead, in the region of distribution of the supra-orbital nerve, the central and largest one exactly over the notch and perhaps one-half inch above it. At this time I did not connect the glandular enlargement with the eruption on the forehead, especially as the patient was subject to eczema, though she herself recognized this as something very different. I believed that a rather severe glandular infection from the parotitis had taken place, and directed her to use turpentine locally long and often, not as a counter-irritant but as an efficient and penetrating antiseptic, capable of killing the poison *in situ*. For the eruption in the face I prescribed a bismuth ointment and hot water. This treatment produced a rapid and complete cure.

CASE V.—A few days later Miss E. M.— came in, presenting almost exactly the same clinical picture as the preceding case, but not quite so severe. There were the same tender glands in front of the ear and in the neck, and on the forehead the same hot, red, painful little swelling over the right supra-orbital notch, like the central lesion in the other case. In this case there was no previous infection that I knew of, though she was in a weakened general condition from too much society and piano practice. Because I knew of no infection I did not deem the turpentine necessary, but prescribed—she was already on tonics—the bismuth ointment and hot water, measures which had proved so successful in my other case, as I thought. But the next day there was no improvement. On the contrary, the pain and burning were more severe and the swelling on the forehead was thickly studded, over an area exactly rectangular and perhaps five-eighths of an inch long by one-third of an inch wide, with minute transparent vesicles. A smaller similar swelling was appearing on each side. I now recognized the herpetic nature of the case, and directed the use of the turpentine as in Case IV., with the result of aborting the later lesions. But, without consulting me, the patient had kept the central lesion covered with court plaster most of the time, thus converting what would probably have healed in a short time into a deep, slowly-healing, rectangular ulcer, leaving at last an unsightly rectangular scar.

In these last two cases it seems the turpentine must either have acted sufficiently as a counter-irritant to have relieved the trouble in the deep-lying trunk of the fifth nerve, or that it was able to penetrate and destroy some infection which had invaded this nerve trunk or its trophic ganglion. Perhaps it acted in both ways at once.

Hemorrhoid.—An inflamed hemorrhoid will often cause exquisite pain. The little mass is bluish, hard, and is with difficulty put back into the rectum, if, indeed, this be at all possible. The treatment is evacuation of the thrombus by a cut radiating from the centre of the anus. Relief is immediate.—*International Journal of Surgery*.

Angina Pectoris.—Sir Benjamin Ward Richardson in the *Asclepiad* says: "From a study of forty-three cases I have reached the conclusion that this affection is a sympathetic neurosis, bearing much the same relation to the sympathetic nervous system as epilepsy does to the brain. Heart lesions and coronary disease are often absent, and when present are probably merely coincidental."

Progress of Medical Science.

Amputation of the Breast for Carcinoma.—Dr. Tansini (*Rif. Med.*, April 5, 1896) calls attention to the fact that many times a cancer of the breast recurs in the apparently healthy skin along the scar. To avoid this possibility, he advocates the removal of the entire skin from the breast and a strip four inches wide extending into the axilla. The author removes all glands and the pectoral muscle. To cover this defect he twists a flap from the back on a pedicle near the axilla and sews it into the wound.

Erysipelas in Infants.—Dr. J. Lewis Smith advises for a child from one to two years old the internal use of four drops of the tincture of the chloride of iron every three hours, either alone or with one of the preparations of cinchona. He applies externally an ointment of ichthyol, a drachm to the ounce of cold cream. High temperature should be reduced by sponging, the wet pack, or the bath. Antipyretic drugs should be employed with caution, only in minimum doses and guarded by a heart stimulant. For delirium the temperature should be reduced. If the delirium does not abate, bromide of potash, chloral, or as a last resort, opium are to be given. In using carbolic acid care must be taken to guard against poisoning. The first evidence of poisoning is shown by the urine leaving a pink stain on the napkin after exposure to the air for half an hour.—*Pediatrics*, May 1, 1896.

Muscular Macroglossia.—Dr. H. v. Ranke (*Jahrb. f. Kinderheilkunde*, xli., No. 3, 1896) names three varieties of the above affection occurring in children: 1. That in which the enlargement of the tongue is caused chiefly by increase of interstitial tissues. There may or may not be atrophy of the ordinary tissue of the tongue. The number of blood-vessels or lymphatics may be much increased, forming tissue resembling an angioma or lymphangioma. 2. There may be an increase of the tongue due to hyperplasia of all the different tissues of the tongue. 3. There may be an increase of the special tissues of the tongue due to hyperplasia of the muscles which make up its structure. The condition generally occurs in conjunction with other congenital deformities, such as abnormality of the intestine, of the arms, or of other parts of the body. It may be related to a general muscular atrophy or to a general muscular hypertrophy or pseudo-hypertrophy. Cretinism or rachitis may be closely connected with the condition.

Infectious Vulvo-Vaginitis in Children.—Dr. Sheffield, in the *American Medical Bulletin*, May 30, 1896, summarizes his views upon this subject as follows: 1. Infectious vulvo-vaginitis in children is of gonorrhœal nature; the diplococcus present in the purulent discharge is invariably identical with that of Neisser, decolorizing by Gram's method. 2. The infection can be conveyed through common privies, baths, beds, clothing, etc. 3. The symptoms accompanying the disease are far less severe than those described in most text-books. 4. Most of the complications are preventable. 5. The value of boric acid or mild silver-nitrate solutions as prophylactics of purulent ophthalmia is very doubtful. 6. Silver nitrate in strong solution is a reliable abortive of purulent ophthalmia, if used in the very earliest stage. 7. The mere presence of gonorrhœal discharge in a small girl, without injury to the genitalia, does not prove that rape has been attempted. 8. Physicians in charge of asylums or similar institutions should be on their guard not to admit girls with vaginal discharge, unless

New York, September 26, 1896.

THE INFLUENCE UPON LEUCOCYTOSIS OF LARGE SALINE INJECTIONS.

THERE is increasing evidence of the usefulness of copious saline injections, either into the subcutaneous connective tissues or into the veins, in the treatment of a number of infectious diseases; but the mode of action is yet a matter of speculation. It is easy to imagine that the good results thus brought about are due, in part at least, to a dilution of toxic substances circulating in the blood and their elimination, especially through the kidneys, and in part to the increased circulatory activity resulting from heightened arterial tension in consequence of the addition to the fluid elements of the blood. The rapidity with which the resulting amelioration of symptoms and reduction of temperature take place in cases that respond to this mode of treatment is, however, indicative of a more profound influence upon the organism, than can be accounted for merely by the increased arterial tension or elimination of toxins. It has been shown that a condition of leucocytosis is a constant concomitant of a number of infectious processes, subsiding with the onset of convalescence. With this thought in mind, Claisse¹ has made a study of the changes in the blood that take place in cases of infectious disease treated with saline injections. The outcome of these observations indicates that a relation exists between the resulting improvement and the state of the blood. Thus, in a case of generalized purulent streptococcus infection, an intravenous injection of fifteen hundred grams of saline solution was followed in an hour and a half by a rise of the temperature from 102.9° to 105.8° F., while the number of red blood corpuscles to the cubic millimetre declined from 3,968,000 to 3,596,000, and the number of colorless corpuscles from 13,547 to 7,804. In the course of three hours the temperature had fallen to 98.6° F. In the case of a man, sixty-four years old, with a diffuse phlegmon of the arm, subcutaneous infusion of a litre of saline fluid was followed by a diminution in the number of red blood corpuscles from 3,565,000 to 3,255,000, and of the colorless corpuscles from 26,660 to 11,346. In a case of profound puerperal infection, an intravenous injection was immediately followed by an alteration in the relation between the red and the colorless blood corpuscles of from 1 to 228 to 1 to 344. It is pointed

¹ Comptes Rendus de la Société de Biologie, 1896.

out that the manifestations following saline injections—depression of temperature, lessening of leucocytosis, amelioration of the symptoms of infection, often with a period of reaction—are analogous to those that have been described as following the employment of the antitoxin of diphtheria. The observations are obviously too few to justify a final conclusion, but they are not without interest or significance, and should be confirmed or contradicted by others. They may further furnish certain prognostic indications, as with proper restrictions the discovery of a leucocytosis may be viewed as pointing to the existence of some infective process.

THE SUNDAY PENALTY OF IRREGULAR FEEDING.

THE American people pride themselves on being enlightened and highly civilized, using their reasoning powers to such advantage that by systems of quarantine, vaccination, etc., they are able to exclude or control almost all epidemics of infectious diseases. These intelligent people would resent a statement that in some of their routine customs they were only slightly above the level of barbarians, yet the unhappy truth remains that such a statement may be made without fear of refutation.

In our evolution from barbarism we have created or established a race of people with whom regularity in eating and sleeping is the fundamental essential to good health. The digestive secretions are poured out and ready for action with the regularity of clockwork, so that a man can tell by his feelings almost the minute at which his dinner hour comes. If this regularity, so long established, is violated and the regular dinner hour is passed without food being ingested, the violator not only suffers bodily discomfort, but an actual injury occurs to the digestive apparatus. The stomach and other secretory organs resemble the muscular system in a certain degree, as they must have a certain amount of work to perform in order to keep in the best working condition. Also, like the muscular system, overexertion leads to disorder, and disuse invites a variety of pathological conditions. But, unlike the muscular system, the digestive organs have been so educated by custom that they require, not only a definite amount of work to perform, but an absolute regularity in the time of performing that work. The gourmand who overtaxes his stomach is certain to meet his retribution. The drunkard who stimulates the mucous membrane of his stomach with alcohol and gives his secretions nothing to act upon in the way of solid food, finds shortly that his stomach refuses to secrete at all, as just punishment for his abuse and negligence. Almost as certain a result, if not so rapid, is sure to follow indiscretions of irregularity in eating. The stomach, having poured out its secretions at the customary time, waits only a short time before it allows such secretions to be absorbed without the accompanying production of nutritious pabulum that goes to assist in the formation of more secretions. After a few such experiences the secretions become less in amount and in activity, even when food is in-

roduced into the digestive tract, and we have resulting indigestion, so common in all communities.

The dyspeptic is cautioned and induced by his physician to take his meals at absolutely regular intervals, not only as a treatment of existing evils but as prophylactic against future disorders. One indiscretion of irregularity in such cases often causes the patient a week of misery. If this regimen is a standard prophylactic with confirmed dyspeptics, how much should any one in our artificial civilization allow himself to deviate from so simple a rule, when an absolutely normal stomach at all times is almost unknown?

Yet this very invitation to gastric disorders is issued every seventh day by ninety-nine per cent. of the people of this country. Once in seven days comes our so-called day of "rest" the day on which the three regular meals at morning, noon, and night are replaced by a vicious system of late rising and abstinence, followed by gluttony. The gastric secretions know nothing of a seventh day of rest. They are ready at the customary six-day morning-breakfast time, but no food comes to them and they are absorbed. A second period of the day comes and the same process is repeated, with the additional injury that from two to four hours after the customary meal the stomach is loaded unusually full of food, whereas the secretion is no longer there in sufficient quantity to digest it. The result is the regulation Sunday afternoon discomfort of gourmandizing, with the accompanying absence of appetite for the evening meal. What wonder that the following day is "Blue Monday!"

The barbarian gourmandizes to-day and fasts to-morrow, and he never has gastric disorders. We still exemplify our hereditary traits by imitating him one day of each week, but unfortunately we have not maintained the barbarian standard of excellence in gastric digestion. It would seem as if our process of evolution had reached a stage where we might expect soon to rise above our prehistoric ancestors in our system of eating. We certainly cannot do so until we do away with our custom of alternate fasting and over-feeding. Monday would lose something of its azure hue and some "digestive-ferment" manufacturers might be obliged to make assignments if such a progressive step were to be taken, but the general satisfaction would in a measure compensate for the damage done these ancient institutions.

THE USE OF ARSENIC IN CHOREA.

We believe the prevailing method of treating chorea in this country is by arsenic, and the usual form in which this drug is administered is Fowler's solution. In France Boudin's solution of arsenic seems to be much employed, and as it is much weaker than Fowler's it is said to admit of easier and more exact dosage. Dr. Jules Comby, of Paris, writing in *La Médecine Moderne*, August 19, 1896, describes his method of using this solution. He puts ten grams of the strength of 1-1,000 into one hundred and twenty grams of a syrupy solution, and gives to a child not under seven years two spoonfuls of this every two

hours for the first day, and increases the amount of Boudin's solution by five grams each day until he arrives at thirty-five grams; then begins to decrease the daily amount by five grams down to zero, when the patient will be found cured. This method is rather more heroic than that pursued here, and we are not surprised to learn that out of twelve cases which the author reports as having been thus treated and cured in the short period of from seven to thirteen days, some had nausea or vomiting, two had notable gastric embarrassment, one had arsenical paralysis (although this disappeared entirely), and one had passing pigmentation of the upper extremities. The treatment which the author says Grancher carries out at the hospital for children in Paris is preferable and is more in line with that practised here, except that he gives Boudin's solution instead of Fowler's. He prescribes four grams the first day, and increases the amount by two grams daily to the point of tolerance, but does not advise going beyond thirty grams a day. Another method of treatment in vogue in Paris is by antipyrin, but that remedy is slower and less reliable than arsenic.

News of the Week.

"The Atlanta Clinic" is now under the editorial management of Dr. Lucien Lofton.

A Member of a Medical Society in Vienna has been expelled for criticising a fellow-member in one of the daily papers.

Dr. William Thayer Smith, professor of physiology in Dartmouth Medical College, has been appointed dean in that institution, to fill the vacancy caused by the death of Prof. Carleton P. Frost.

The New Building of the medical department of the Creighton University at Omaha, Neb., is nearing completion. It is a handsome four-story and basement building. This and the St. Joseph's Hospital are gifts of Mr. J. A. Creighton.

The Russian Physician, so it is said, considers it beneath his dignity to send an account to a patient, but leaves it to the latter to pay what he thinks proper. Many think it proper to pay nothing.

The Floating Hospital of St. John's Guild carried during the season of 1896, 46,253 women and children. Over seven hundred sick children were treated, without a death taking place on board. Four trips only were omitted between July 8th and September 3d, and these were due to bad weather.

"Official Cheek" is what the editor of the *Cleveland Journal of Medicine* calls the request of the treasurer of the American Medical Association for five dollars in payment of the annual dues for 1896. As the association has declared that the members of the Cleveland Medical Society are no longer to be recognized as in good standing in the association, this characterization of a demand for dues would not appear to be unjustified.

Dr. George A. Gibson is to assume editorial control of the *Edinburgh Medical Journal* with the new year.

A New Consumption Cure is that of Dr. Langheld. It is claimed that the remedy kills the germs by carrying ozone to them. It has been tried in Berlin and Vienna, and it is reported that some of the patients are still alive.

The Bender Hygienic Laboratory, in connection with the Albany Medical College, is now completed, and will be ready for use during the coming session. Special dedicatory exercises will be held during October. Dr. George Blumer, late of Johns Hopkins University, has been appointed director of the laboratory.

"**The Charlotte Medical Journal**" has recently changed its appearance by enlarging its pages and making double columns, thus increasing very considerably the amount of reading matter. Our esteemed contemporary is evidently enlarging its sphere of usefulness very materially, and we congratulate its talented editors upon the well-deserved success of their undertaking.

A Polish Medical Society has been organized in Chicago and will be known as the "Towarzystwo Lekarzy Polskich." Drs. E. Czerniewski, D. Dowiat, M. Orglert-Kaczorowska, J. P. Kaczorowski, M. P. Kossakowski, W. Kuflewski, J. Piszczak, W. J. Siemionowicz, W. Statkiewicz, B. F. Strzyzowski, J. Ziolkowski, and R. L. Lande are the founders of the society.

Vaccination and Railway Accidents.—One of the arguments used by those who oppose the compulsory vaccination law in England is that vaccination is more dangerous to life than is railway travel. There is one fatal termination to every 14,159 cases of vaccination, while of railway travellers only one is killed among every 35,500,000.

Cheap Doctoring.—Two private hospitals have recently been established in St. Louis, in which the members of the association supporting them may be treated free. The fee for membership in the association is fifty cents a month. A new health-insurance society in California is cheaper than that, as it provides free medical attendance to all who will pay five dollars a year.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending September 19, 1896. September 14th.—Medical Inspector Daniel McMurtrie promoted to medical director from September 3d. September 18th.—Surgeon L. G. Heneberger detached from naval hospital, Widow's Island, Me., and ordered home to await further orders.

A Campaign against City Noises has been begun by Health Commissioner Kempster, of Milwaukee. The noisiest thing of all and the most trying he thinks is the church bell. Another nuisance that is useless and ought to be abolished is the factory whistle. The effect of these and other noises, he says, is greatly to

injure health and to shock and irritate the sick and those suffering from nervous troubles. He proposes to stop these noises, if he can, and we wish him a full measure of success.

Ammonia in Alcoholism.—Dr. Baratier recommends in *El Siglo Médico* the addition of ammonia to wine or liquor in order to produce a distaste for alcoholic beverages. After a few doses the disgust to the mixture becomes so intense that even the sight or smell of wine is unpleasant.

Medical Society of the State of New York.—The business committee of the Medical Society of the State of New York, recently appointed, consists of the following members: Dr. Seneca D. Powell, 12 West 40th Street, New York, chairman; Dr. Willis G. Macdonald, 27 Eagle Street, Albany; and Dr. Ernest Wende, 471 Delaware Avenue, Buffalo. Communications regarding papers to be presented at the next meeting of the society, to be held at Albany, January 26th–28th next, may be addressed to either member of this committee or to the president of the society, Dr. James D. Spencer, of Watertown.

Quarantine has been finally abolished in the British Islands. For many years there has really been none, yet two vessels with a full staff of medical officers were kept on the south coast of England. There was nothing to do at the station, but it was maintained from year to year, apparently because it never occurred to any one in Parliament to do away with it.

Clergymen and Physicians.—An amusing debate is being carried on in the columns of *The Medical Times* concerning the question of taking fees from clergymen in payment of medical services. One writer, "A Country Parson," who heaped abuse on all "medicos" who would not give him what he called "colored water" for nothing, was reminded by another correspondent that "in our great hospitals the maligned 'medicos' unreservedly—too unreservedly—and gratuitously render to the poor services which, if estimated by the tariff obtaining in their private work, would find their expression in millions of pounds per annum. The chaplain, whose duty it is to administer that consolation which is 'without money and without price,' absorbs a respectable amount of the hospital funds."

Epidemic Disease in Cuba.—The latest published reports of the Marine Hospital Service state that there is no abatement of yellow fever in Cuba, nor is the disease less virulent than it has been all summer. The United States sanitary inspector at Santiago de Cuba, however, reports that small-pox is steadily decreasing, and expresses the belief that in about a month the epidemic will be practically over. Concerning yellow fever, he writes that the disease is causing many deaths among the soldiers, and if the records do not show this it is because the deaths take place in the hospitals outside the city and in the detachments in the surrounding villages. At the Daiquiri mines, for example, the inspector says that he has the positive information that there is about one death from yellow fever daily.

Generous Provision for Free Beds.—By the will of the late Dr. A. H. McAdam, of Philadelphia, the income of \$5,000 is bequeathed to a sister, upon whose death the principal is to revert to the Episcopal Hospital, for the establishment and maintenance of a free bed, to be named, after the testator's wife, as the Anna W. McAdam bed. The sum of \$4,000 is to be held for the benefit of another sister, upon whose death it, together with an additional \$1,000, is to be given to the Hospital of the University of Pennsylvania for the endowment of a free bed to be known as the Dr. Alexander H. McAdam bed.

Typhoid Fever is unusually prevalent in Chicago, Denver, and various other cities. In Chicago, we learn from the *Journal of the American Medical Association*, on September 4th seven people died from typhoid fever, breaking the record since 1892. The health department says the prevalence of the disease is due to impurities in the drinking-water. During August of this year typhoid claimed sixty-four victims, against fifty-nine for the corresponding period of 1895. About five hundred cases are reported at present in that city. In Denver, the *Colorado Medical Journal* says, there is now raging an epidemic of typhoid fever which has more victims and a greater fatality than any epidemic since 1892. It is probably due to a polluted water supply. A number of physicians in the city are affected.

A Hospital for Tuberculosis in Philadelphia.—At a recent meeting of the Philadelphia board of health, the president of that body, Dr. William H. Ford, proposed the establishment of a hospital for tuberculous patients, under the direct care of the board of health, in analogy with the care of cases of contagious disease at the Municipal Hospital. It was suggested that the old Lazaretto Station in Delaware County, now no longer used and the sale of which has been authorized, could be well devoted to the purpose in hand. A resolution was accordingly offered, requesting the repeal of the ordinance authorizing the sale of the Lazaretto property, as well as authority for the establishment of the proposed hospital and an appropriation of \$19,500 for maintenance. Dr. Ford's argument was that as tuberculosis is an infectious disease, whose spread may be limited by the adoption of certain precautionary measures, while many die from the disease as a result of ignorance, neglect, and want, a grave responsibility devolves upon the municipality, which has been only partially and inadequately met through the efforts of philanthropic societies and individuals, and principally in the way of establishing hospitals for the sick. "If any progress is to be made in checking the ravages of tuberculosis, isolation and treatment in hospitals must be depended upon as a most important means to this end. The municipality is obligated to provide for the indigent sick, but especially urgent is this demand when such sick persons, unprovided for, jeopard the public health." The contention is made that tuberculosis "should be under the supervision of the health authorities, just as other dangerous diseases are, and the day is not far distant when this disease will be required to be reported to the board of health, as

other contagious diseases are now under the law. But time is necessary for the consent of the people to this new requirement. It would, therefore, seem that the hospital contemplated should most appropriately be placed under the supervision of the board of health, in conformity with the provisions of the law and as a means of simplifying the management of the disease. The main question, however, is the prompt organization of such a hospital, for which the opportunity is very favorable. The question of administration is of secondary importance."

Dedication of a Hospital Annex at Trenton, N. J.—A new annex to St. Francis Hospital at Trenton, N. J., was dedicated on September 17th, the blessing being offered by Bishop McFaul, assisted by a number of priests. The new building is a four-story structure, 50 x 65 feet, with a single-story addition twenty-eight feet square, fitted up as one of the best-equipped operating-rooms in the country. The new building cost \$34,000 and will add forty-five beds to the present capacity of the hospital, which is one hundred and five beds.

Obituary Notes.—DR. THEODA WILKINS, of Pomona, Cal., died on August 28th from injuries received in a runaway accident. She was a graduate of the Woman's Medical College of the New York Infirmary in 1885, and was an active member of the Pomona Valley Medical Society.—DR. JAMES EDGAR CHANCELLOR, of Charlottesville, Va., died on September 9th. He was born in Chancellorsville in 1826, and was graduated in medicine from the Jefferson Medical College in 1848. He served as surgeon in the Confederate army, and at the close of the war settled in Charlottesville. He was a member of the State examining board of Virginia, of the State society, of the American Medical Association, and of the Public Health Association.—DR. CHARLES BERNACKI died at Schandau, Saxony, on September 17th. He was born at Starasol in Galicia in 1812, and was graduated in medicine from the University of Vienna in 1839. About ten years later he came to New York where he practised for the rest of his life. A widow and a daughter survive him.—DR. THOMAS R. MCCRESSON died at his home at City Island on September 18th. He was born in this city in 1851 and was graduated from the New York University Medical School in 1879.—DR. STEPHEN CONGAR died in Pontiac, Mich., on September 18th. He was born in Newark, N. J., eighty-six years ago, and after obtaining his degree from the College of Physicians and Surgeons in this city, began the practice of medicine in Newark. He always took a great interest in the public schools, and served as member of the school committee, superintendent of schools, and president of the board of education for many years. In 1859 he removed to Pontiac, where he resided up to the time of his death.—MR. WICKERSHEIMER, the inventor of the preparation bearing his name for preserving pathological specimens, died in Berlin on September 4th.—DR. W. L. FRISBIE died at his home in Potterville, Bradford Co., Pa., on September 15th, at the age of sixty-two years.

Society Reports.

SECOND INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

Held at Geneva, August 31 and September 1, 2, 3, 4, and 5, 1896.

IN the afternoon of the first day there was a reunion of the permanent international committee and the organizing members of the congress. In the evening a reception was given at the Palace Eynard by the Conseil d'État of the Swiss Republic and the Conseil Administratif of the city of Geneva.

The Surgical Treatment of Pelvic Suppuration was the first set subject for discussion. This was opened by DR. BOUILLY, of Paris. From the point of view of surgical interference, he said, pelvic abscesses may be classified as follows: (a) Cellular abscesses, perimetritis, periuterine phlegmons. (b) Abscesses of the ovaries or the tubes, pyosalpingitis, and suppurative oovitis. (c) Primitive peritoneal abscesses, pelviperitonitis, suppurative hæmatocele. (a) Simultaneous suppurations of various pelvic organs, constituting purulent collections or complicated with fistulæ, bursting either through the skin or into the neighboring cavities, or in various places, at the same time.

An exploratory puncture offers us the only certain means of diagnosis. The three principal methods of treatment of pelvic suppurations are: 1. Simple incision followed by drainage through the abdominal or vaginal wall. 2. Opening or ablation of the suppurating cavities by laparotomy. 3. Opening or ablation of the suppurating cavities through the vagina, by means of previous vaginal hysterectomy with or without morcellation of the uterus. 4. As derived from these principal methods can be considered: (a) The ablation through the vagina of small unilateral collections, with preservation of the uterus and appendages of the opposite side. (b) The simultaneous ablation of the appendages and uterus through the abdomen.

The method of election is simple incision followed by drainage: (a) For the opening of acute pelvic abscesses originating in the cellular tissue. The incision must be made where the collection bulges out either on the abdominal wall or in the vagina. (b) For the opening of primary peritoneal collections, either acute or subacute, or those following peritoneal infection, after operation, abortion, childbirth, or gonorrhœa. (c) For the opening of suppurative hæmatocele. (d) In the treatment of pelvic encysted abscesses of the appendages. In those cases it can be applied safely only when the sac is unilateral, thin-walled, fluctuating, and lying low by the side of the uterus, or when it can by pressure on the hypogastrium be brought into contact with the vaginal wall. The failure of the vaginal incision does not prevent the success of ulterior vaginal hysterectomy.

Laparotomy and vaginal hysterectomy as applied to the treatment of pelvic suppurations are not rival methods; both have their indications and advantages. When the patient is young and whenever there is any doubt as to the bilaterality of the lesions, laparotomy, which affords the sight of the opposite side, is to be selected. Laparotomy shall be selected in case of doubt as to the nature of lesions (possible existence of an ovarian simple or dermoid cyst or of extra-uterine gestation). However, the matter is generally settled in such a case by the fact that the purulent collection is unilateral. In the cases of bilateral lesions, when there is any doubt as to the two operations, the situation of the two purulent sacs in regard to the uterus and the vaginal culs-de-sac becomes a leading factor in the indications. With these excep-

tions founded upon the unilateral seat of the lesions, uncertainty about the nature of this lesion, the high position of the abscess, vaginal hysterectomy applied to the treatment of pelvic suppurations allows the pus tubes, the small pyosalpinx, the suppurating ovaries to be removed. It allows us to reach and cure lesions against which laparotomy is either powerless or too dangerous. It is the method to be selected in the treatment of large adherent sacs, which cannot be enucleated. It is better than any other method in chronic suppurations of the periuterine cellular tissue which have discharged spontaneously, most often communicating with neighboring organs. In these cases the operation must almost always remain merely one for evacuation. Ablation of the uterus gives us ideal drainage, owing to which the collections are emptied. For this reason, insisting upon the extirpation of the sac would be removing from the operation all the advantages of its simplicity and benignity, and failing to recognize one of the principal rôles of vaginal hysterectomy in the treatment of pelvic suppurations.

A good many laparotomists recognize nowadays the necessity of ablation of the uterus. This ablation insures firstly perfect drainage; secondly, it prevents future troubles which may be brought about by the uterus if left *in situ*; and so immediate cure is more common and the ultimate results are better.

On the whole, the speaker held that, in most cases in which simple incision was not possible, vaginal hysterectomy is the best method of treatment of pelvic suppurations; and laparotomy is to be performed only when contraindications to vaginal hysterectomy exist.

DR. HENROTIN, of Chicago, advocated conservative vaginal work. He believed that patients undergoing radical surgical operations are oftener cured of the operation than of the disease; that patients have often been cured of the disease without radical operation; that an immediate opening through the posterior vaginal fornix in the first week of an acute pelvic suppuration will give a large percentage of cures in cases which under the poultice-and-douche treatment would terminate fatally. He supported this claim by citing numerous statistics.

DR. SÄNGER, of Leipsic, said that the German gynecologists uphold the following general principles: 1. There must be strict indications for the operation; 2, the intervention must be as conservative as possible; 3, the bacteriological, clinical, and anatomical diagnosis must be our guide in the choice of the intervention in any given case.

Most surgeons discard vaginal hysterectomy and hysterosalpingo-oöphorectomy, preferring more conservative methods and abdominal operation. Hysterectomy is not the only thing to be considered in the treatment of pelvic suppurations.

He then reviewed the special methods of treatment:

Puncture is limited to inveterate cases of encysted abscesses or single purulent collections in the closed organs. Success can be expected only when the pus is sterile.

Incision applies:

(a) To extraperitoneal purulent foci. The proceeding ought to be limited to real purulent collections.

(b) To intraperitoneal purulent foci; this operation may be called simple colpocœliotomy.

The simplest proceeding consists in the incision of the vagina by means of the thermo-cautery and opening of the abscess with a dressing forceps. There is no necessity for irrigations, or for filling the cavity with gauze immediately after the operation.

(c) Cœliotomy is always indicated in purulent collections which through their size amount to real tumors, as well as in suppurating cystic and other

neoplasms. Simple cœliotomy and drainage suffices in encysted foci, remnants of purulent (and tuberculous) peritonitis, if however the removal of the appendages or of other suppurated organs is not demanded.

The difficulties as to the choice of an operation in connection with the opening of the abdominal cavity, in suppurated diseases of the appendages, have recently been enhanced through the increased number of the proposed operative measures. The speaker then gave a list of all these operations, of which there are two main sorts, vaginal and abdominal.

The recognition of the harmful influence of premature extirpation of ovaries or of complete extirpation of all the internal generative organs, especially in younger persons, has led to conservative vaginal and abdominal operations.

After reviewing at great length all these methods of operation, their indications, their technique, and their dangers, the speaker formulated the following conclusions: Advocates of the different operative methods ought not to claim an absolute superiority for their own proceeding. Every appropriate treatment may be justified and in every individual case it is far better to take into serious consideration the special advantages offered by each one of the methods. Let every one strive to perfect his own operative methods, while recognizing at the same time the value of others; the result will then be improvement and progress.

The Surgical Treatment of Retrodeviations of the Uterus was the second subject discussed.

DR. OTTO KÜSTNER, of Dorpat, opened the discussion. Although no operation which has ever been proposed for uterine retroversions, he said, can return the uterus and adnexa to their normal position, we should prefer the new position, artificially produced, to the former retrodeviation; for it gives to the uterus to the same extent its normal mobility. The formation of adhesions with neighboring organs is thus prevented, so is the prolapsus.

It is necessary to differentiate the reducible from the non-reducible retrodeviations; the latter must be first made movable.

In our procedures for stretching the adhesions we must not open the abdominal cavity when the adhesions are not very resistant or very large. Massage or Schultze's method will suffice. If the adhesions are too numerous or too resistant, we should open the abdomen in order to free the uterus as well as possible.

The opening into the abdomen may be made through the anterior or posterior cul-de-sac, as well as through the abdominal walls. No doubt with laparotomy, we can have a fuller view of the state and size of the adhesions. Therefore it has great advantages in the careful treatment of adhesions and of adnexa, which are always more or less affected. Colpotomy is much less accurate, and gives less complete results. To avoid wounding the neighboring organs, the methods which have for their aim the fixation of the uterus in a new position must keep the uterus in good situation and must not interfere with the healthy functions of the uterus.

The results obtained by ventro-fixation, vagino-fixation, abdomino-vesical fixation, and by Alexander's operation show that these operations can keep the uterus in good position. The same can be said neither of recent modifications of these methods, nor of Säger's retrofixation.

The normal function of the uterus is but slightly, if at all, disturbed by ventro-fixation, Alexander's operation, or vesical fixation. It is, on the contrary, injuriously affected by vaginal fixation when this extends to a large surface of the anterior aspect of the uterus. Therefore we should not perform vagino-fixation on women in the child-bearing period. When patients

cannot conceive, this operation gives very good results. When the adhesions are large, the best operation is laparotomy, followed by rupture of the adhesions with Paquelin's cautery, with scissors, or with the fingers, and ventro-fixation after Olshausen's method.

The best operation for reducible retrodeviation is Alexander's, for it gives in every case a nearly or really normal position to the uterus.

DR. POLK, of New York, followed with a paper, of which the following is a summary: Retrodeviations, especially in a uterus capable of pregnancy, should not be healed by any operation which fixes the fundus or body to the abdominal wall or to any contiguous structure, such as the bladder or vagina.

In such cases uncomplicated retroversions should be treated by Alexander's operation or by intraperitoneal shortening of the round and utero-sacral ligaments, operating through the vagina. Retrodeviation complicated by adhesions should be healed by intraperitoneal shortening of the round ligaments, and when necessary of the utero-sacral also, operating, when possible, through the vagina. Alexander's operation may be applied to the versions after rupture of the adhesions through a colpotomy, provided the round ligaments have not adhered to their sheaths, as sometimes happens because of the antecedent perimetritic inflammation.

Retrodeviations in a uterus deprived of its appendages should be treated by intraperitoneal shortening of the round ligaments, and of the utero-sacral also, when needed.

Retrodeviations after the menopause should be treated by intraperitoneal shortening of the round ligaments, and of the utero-sacral also, the operation being conducted through the vagina, if possible. If there are no adhesions and the uterus is not atrophied, Alexander's operation will suffice.

Whenever they are elongated, so as to form a direct factor in retrodeviations, the utero-sacral ligaments should be shortened, the vagina being the best possible route for the procedure.

The speaker then described the operation for shortening the round and utero-sacral ligaments as follows: (1) The anterior vault of the vagina is opened as in anterior colpotomy, the vesico-uterine space is entered, the uterus and appendages are freed from adhesions if such exist, the uterus is anteverted, and the fundus is brought into the vagina. The round ligament with its peritoneal sheath is encircled with a silk suture, as far out from the uterus as will permit the easy attachment of the part encircled to the uterus at the origin of this ligament. This folds the ligament inward upon itself, presenting of course two loops; one is always sutured to the uterus; the other is now sutured to the round ligament outside the folded section, which section in turn is encircled with the third suture. Special care must be taken to avoid the tube, the suture being passed as close to the ligament as possible. The manœuvre is repeated on the opposite side, the uterus is replaced in the peritoneal cavity, and the wound is closed with catgut, the peritoneum being sutured first and then the vaginal wall.

(2) The posterior vault of the vagina is opened by a transverse incision coincident with the utero-vaginal junction, and extending fully to the cornu of its lateral aspect upon both sides. Douglas' cul-de-sac is entered and a stout silk suture is passed over the utero-sacral ligament at about its middle. This is done on both sides, the ligaments being put on the stretch to facilitate the procedure. One end of each suture is now passed through the vaginal wall, upon its lower side, at the outer ends or angle of the cut, and is then firmly tied. This draws the cervix upward and backward to the extent of about half the length of each

utero-sacral ligament. The wound in the vagina is closed with catgut, and the sutures holding the utero-sacral ligaments are left long, the tube being removed at the end of two weeks. The patient is confined to bed at least three weeks; no pessary is used. Special care is to be taken to keep the bowels open and to avoid distention of the bladder; patients with prominent abdomen should subsequently wear an abdominal supporter.

DR. S. Pozzi, of Paris, said that the clinical conditions known as retroversion and retroflexion do not form a distinct pathological affection. They are considered as special affections only through an old tradition, which should to-day be revised.

Retrodisplacement of the uterus, either simple or with flexion, is observed in two entirely different conditions, viz.:

(a) Relaxation of the ligaments, without adhesions, due to a former perimetro-salpingitis. This is the movable retrodisplacement.

(b) Posterior adhesions, especially around the adnexa, following a perimetritis or a peri-oöphoro-salpingitis. This is the fixed retrodisplacement and is by far the most frequent.

For movable retrodisplacements the term mobility of the uterus should be substituted for those of retroversion and retroflexion. In point of fact the backward displacement is simply in this case the most natural position of a uterus which has lost its fixation and consequently its normal anteversion. But this abnormal displacement is in itself the cause of slight symptoms; the principal phenomena of nervous and reflex origin are independent of the direction of the displacement and are due to the mobility. They persist when the uterus is momentarily put back in position without being kept there. They appear to be due to a bad equilibrium in the abdominal statics, to a real pelvic enteroptosis.

All surgical treatment of these cases which aims to fix the uterus, when replaced, by a limited point of its surface, will give only temporary results. The constant traction on the point of fixation produces relaxation, and is the cause of unsuccessful results which usually after a variable lapse of time follow Alexander's or similar operations.

The rational treatment of movable retrodisplacements, or rather of mobility of the uterus, is complex and should provide for the various indications present. These are: to cure the metritis, which is very frequent in such cases, by proper treatment (curettage, amputation of the cervix, etc.); to restore the perineum, often ruptured or relaxed, by a large and extensive plastic operation; to apply a pessary which fixes the cervix by distending the posterior cul-de-sac as well as a hypogastric bandage which regulates the intra-abdominal pressure.

The treatment of fixed retrodisplacements of the uterus is that of the lesions which have produced it and keep it up.

Many fixed retrodisplacements are indolent, and become tolerated, but morbid symptoms occur if the uterus is again the seat of metritis. The operative treatment of the uterus by proper means will be sufficient to cause the accidents to disappear if the adnexa are only slightly or not at all diseased.

In other cases clinical examination shows that the lesions predominate in the adnexa and that a metritis coexists. Laparotomy is there indicated.

If only slight lesions of the adnexa are found, such as a sclero-cystic ovaritis without obliteration of the tubes serving as a starting-point for adhesions, conservative operations should be performed, such as ignipuncture and partial resection of the ovary according to the given case.

The uterus will of itself return to its normal position after destruction of the adhesions.

There are cases in which the best treatment of a retrodisplacement is vaginal hysterectomy. These are cases of old bilateral lesions of the adnexa, complicated by chronic metritis with hypertrophy of the uterus. In such conditions, extirpation of the adnexa through the abdomen after destruction of the adhesions, leaves a large and heavy uterus, which will soon be again retrodisplaced in the posterior vaginal cul-de-sac. A complementary abdominal hysteropexy can of course be performed at the time of operation and later a cure and involution of the organ can be brought about by curettage and amputation of the cervix, and lastly repair of the perineum, if it is relaxed and insertion of a pessary. But this practice is much more complicated and quite as serious as vaginal hysterectomy.

The Best Method of Closing the Abdomen.—DR. BANTOCK, of London, opened this discussion with an elaborate paper, of which the following were the conclusions:

1. Bacteria do not play any part in the production of suppuration, but are the result and not the cause of the conditions under which they are found. Hence abscess in the wound or in the track of the sutures is not due to the entrance of "germs" or fully formed bacilli, but in the former case to the presence of matter acting the part of a foreign body, and in the latter to strangulation of the tissues by too tight constriction by the suture.

2. In ordinary cases the simple interrupted suture alone is sufficient for all practical purposes.

3. In very thin or very fat subjects it is desirable to close the peritoneum separately by continuous suture, while the remainder of the wound may be closed in one or two stages.

4. For the simple interrupted suture silkworm gut forms the best material, while for the buried suture catgut not chromicized will probably be found preferable.

DR. LA TORRE, of Rome, continued the discussion. Post-operative hernia he defined to be the issue of viscera through an opening of the abdominal wall; more commonly through the musculo-aponeurotic plane. This accident was very common when the abdomen was closed by the extraperitoneal method, but it has become rarer now that we close the abdomen after the intraperitoneal plan, or after the extraperitoneal method with Durante's modification. Three principal factors are concerned in a good closing of the abdomen, viz., the incision, the material of the suture, and the mode of suturing.

The most important factors are the incision and suture of the musculo-aponeurotic plane, *i.e.*, the place where the tissues are to be cut and sutured.

Hernia is often produced by suturing the aponeuroses of the linea alba instead of suturing the substance of the muscle.

When the patients are still in the childbearing age, the operator should always suture the muscles. It is better in these cases to cut into the linea alba; then, before suturing, to cut off the aponeurosis of the linea alba up to the internal borders of the recti, and to unite by suture the muscular sheath and the muscle itself.

With old or sterile patients incision and suture in the linea alba alone might be recommended, when it is possible to obtain, during the operation and afterward, the conditions necessary to a good cicatrization.

In case of secondary closing of the abdomen, incision and suture have always to be made in the substance of the recti.

The most commonly used suture materials are silk, catgut, silver wire, and wormgut. Although all are good, silk and catgut are to be preferred.

The best mode of suturing is always in superposed rows of suture, and suture *en surjet* is to be preferred to separate stitches; the peritoneum, the aponeurosis of the linea alba (when this is not cut off), the deeper layers of the sheath of the recti, the muscles, the superficial layers of the muscular sheaths, and the skin with the subcutaneous tissue must be sutured separately.

Treatment of Eclampsia.—This was the final subject for discussion. The first paper was by DR. CHARPENTIER, of Paris. Every albuminuric pregnant woman, he said, being exposed to eclampsia, and milk diet giving marvellous results in albuminuria, we should very carefully examine the urine of pregnant women, and, when we find albumin in it, even in minute quantity, we should at once order an exclusive milk diet. This is *par excellence* the prophylactic treatment of eclampsia. When a woman has cedema without albuminuria, it is advantageous, if not absolutely necessary, to prescribe milk diet. During an eclamptic attack, if the patient is strong and cyanotic, we must first bleed her three hundred to five hundred grams. We may also give inhalations of chloroform and set up diuresis by hypodermic injections of artificial serum.

If the patient is delicate, if the cyanosis is but slight, if the fits are not frequently repeated, the chloralic medication will suffice.

We must wait till the labor begins spontaneously and let it go on undisturbed whenever it is possible. When, the labor having begun spontaneously, the case does not terminate by itself, on account of the contractions being too feeble or too slow, we must deliver the patient by forceps or by turning, followed by extraction, when the child is living; by cephalotripsy, basiotripsy, or cranioclasia when the child is dead.

We must wait without performing such operations till the state of the maternal parts (full dilatation or at least dilatibility of the cervix) permits us to interfere harmlessly, *i.e.*, without violence, consequently without danger for the mother.

Labor should be induced only in exceptional cases.

Cæsarean section and "accouchement forcé" are to be absolutely rejected as usual methods for the treatment of eclampsia. We must have recourse to these operations only in case of failure of every other means and when the mother seems on the point of dying.

DR. F. HALBERTSMA, of Utrecht, continued the discussion. He thought that in the therapeutics of eclampsia the most important question to decide was whether, at the termination of the pregnancy or at the beginning of labor, we must wait or accelerate the labor.

In the cases mentioned above, the active interference of the physician is usually indicated: When the prognosis seems very serious on account of complete anuria, or on account of the frequency and intensity of the convulsions; when nothing shows that the labor is about to begin; when, the labor having begun, the particulars of the case lead us to expect it to be difficult and tedious, as it is for primipara; when the patient is aged; when the pregnancy is multiple; or when the pelvis is narrow.

DR. MANGIAGALLI said that prophylaxis is most important; this consists in a milk diet assisted by the means capable of disinfecting the intestinal contents, of increasing diuresis, of improving the functions of the skin, and of stimulating the action of the heart.

Medical treatment, whether blood-letting or purging, the use of morphine, chloral, chloroform, veratrum viride, or diaphoresis must be essentially symptomatic. It constitutes in every case the only possible treatment in eclampsia post partum. Blood-letting followed by subcutaneous or intravenous injections of

physiological solution of chloride of sodium is a therapeutic method which rests on rational considerations and has clinical facts in its favor.

The prompt evacuation of the uterus constitutes the most important point in the treatment of eclampsia occurring during labor.

In case of eclampsia during pregnancy we must induce labor by rupture of the membranes, and administer morphine, chloral, or veratrum viride in strong doses; these measures are the more useful the sooner they are administered after the convulsions have set in. If the case is serious, the danger imminent, if in spite of the rupture of the membranes labor does not progress, or if the neck of the womb is shortened and softened, forced dilatation will be better than deep incisions of the cervix. In the cases of the same category in which conditions exist which render dilatation or incision particularly difficult, Cæsarean section will be justified, especially if the fœtus is at term and living. Every intervention must be made under deep chloroform narcosis.

DR. JOHN W. BYERS, of Belfast, defined eclampsia as that condition in which convulsions arise suddenly during pregnancy or labor, or after delivery. He excluded those cases in which fits occur in a pregnant epileptic, or when they arise from gross intracranial disease. While the etiology and pathology of eclampsia are still obscure, he directed attention to a change of opinion among British observers on two points: 1. The extreme view that the convulsions in all cases are due to renal disease is being abandoned. 2. Much greater importance is now attached than formerly to the influence of the fœtus as a factor in the causation of the fits.

Taking everything into consideration, the most probable hypothesis is that the convulsions are due to the influence on the nervous system of a poison which arises as a product of ordinary tissue metabolism (elaborated in part by the mother and also by the fœtus), and which in ordinary cases, provided it does not accumulate in too great an amount and the eliminating organs are working properly, is got rid of without any ill effects. When, however, these organs have too much to do, as when the muscular efforts of labor increase the work of the kidney, then the poison is not excreted and its increased accumulation affects the nerve centres; or the same thing may occur if the function of the eliminating organs is interfered with, as in constipation, or when the kidney is in that condition which Leyden has described as being peculiar to pregnancy, or when there are changes in the renal organs and liver in the form of a parenchymatous degeneration, produced, it may be, by the poison in its circulation, through them. Accepting the above explanation as a working hypothesis, he considered the treatment of eclampsia under the four heads:

1. The convulsions should be treated with morphine (hypodermically). The patient is to be placed on her side, to prevent the entrance of fluids into the larynx and lungs (pulmonary cedema being a common cause of death in eclampsia). Care should be taken that she does not injure herself; she should be kept warm, purged freely, allowed no liquids, and, accordingly as she is conscious or not, between the fits, a warm or vapor bath should be used.

2. Efforts should be made to eliminate the poison by purgation, hot baths, keeping the patient warm, and by the non-administration of liquids.

3. If labor has not set in, the convulsions are to be treated, but premature uterine action should not be induced. When labor has begun, and the patient is in the second stage, chloroform should be administered and delivery rapidly completed. In the first stage, with strict antisepsis, labor may be expedited

by the hot douche and by the use of Barnes' or de Ribes' bag, if the cervix is dilatable. If the cervix is rigid, this should not be done.

4. In the prophylaxis of eclampsia, rest, milk diet, purgatives, and warm baths give the best results.

DR. THEOPHILUS PARVIN, of Philadelphia, said that puerperal eclampsia is in almost all cases caused by toxæmia. Those instances in which the disease is apparently reflex in origin may be explained as resulting from an increased nervous excitability, consequent upon blood changes, and without such changes irritation would not cause convulsions. The bladder filled with urine, the loaded bowel, pain are not the essential causes; they are only exciting causes. The spark does not cause an explosion if there be no gunpowder.

He regarded that treatment as best which acts upon the essential cause and at the same time meets symptomatic indications.

He believed that veratrum viride is better than any other drug yet employed, and that it does affect the essential cause, as well as to a great degree the symptomatic conditions, for it notably reduces the frequency of the pulse, and convulsions occur only in very exceptional cases if the pulse be kept at 60 or less; it increases the activity of the skin; it reduces the temperature; and it causes increased secretion of urine. Finally, the recovery of so large a number of mothers, about ninety-two per cent., when veratrum viride is employed proves the value of the remedy.

FRENCH CONGRESS OF ALIENISTS AND NEUROLOGISTS.

Held at Nancy, August 1-6, 1896.

Auditory Hallucinations.—DR. VALLON, of Paris, read a paper with this title, in which he expressed the belief that all hallucinations of hearing were of cerebral origin. He made this division of sensorial troubles relating to hearing: 1, those in which the starting-point was in the brain—true hallucinations; 2, those in which the starting-point was peripheral. But all true hallucinations were cerebral; others were rather illusions.

DR. BALLET said a normal perception assumed a peripheral impression by some sense (hearing, for example), conducted to a cortical centre. Little did it matter in the explanation about the seat of the cortical auditory centre, but rather what part it played. Of normal auditory perception there were three forms: 1, brute perception or mere recognition of sound; 2, discriminating auditory perception; 3, verbal auditory perception. A peripheral auditory trouble might cause a hallucination, but not in everybody.

DR. RÉGIS, of Bordeaux, remarked that the general view seemed to be that auditory hallucination implied the intervention of a cortical centre, but according to his idea the sensory apparatus should be recognized as the exciting cause. Hallucination was often a cortico-sensorial phenomenon.

Crossed Heredity by Experimentation.—DR. CROCQ, JR., of Brussels, said in this communication that crossed heredity had been contested of late, principally by André Samson, who had characterized it as purely chimerical. While Crocq did not regard it as constant, nevertheless he thought its existence was real. Among chickens and pigeons he took two virgin animals of different race, and of twelve of their young eight were males and partook of the maternal characteristics, four were females and partook of the paternal characteristics. This experiment of cross-breeding with different races of pigeons and different races of chickens gave similar results whenever the pair was entirely virgin.

Melancholia, Paralysis: Craniectomy, Evacua-

tion of Cyst, Cure.—DR. AUGUST VOISIN reported the case of a woman, aged twenty-one, taken three years before with intense pain in the left temporo-facial region, gradual development of morbid fears and suicidal tendency, convulsive attacks, projectile vomiting, and hemiparesis affecting the face and limbs on the right side. Craniectomy was performed on the left temporo-parietal region, fifteen by seven centimetres. There was pachymeningitis, and in the ascending frontal and parietal convolutions a cyst was evacuated, four centimetres in diameter, filled with serum. From the first hour after the operation the cephalalgia, together with the suicidal tendency and paresis, disappeared permanently.

Spasmodic Paraplegia.—DRS. RAYMOND and A. SOUQUES, of Paris, reported two cases of progressive spasmodic paraplegia in sisters, aged nineteen and fifteen respectively. The disease had started insidiously and without known cause, in the former at the age of nine, in the latter at the age of twelve. In the elder sister the spasmodic paraplegia began in the right leg and went on to implicate in succession the left leg and upper extremities. By the age of fifteen she was unable to walk. In the other case only the legs were as yet affected. The knee reflex was exaggerated. Strümpell had made one autopsy in this disease, and found combined sclerosis, implicating the pyramidal, Goll, and direct cerebellar columns.

Partial Epilepsy in Acromegaly.—DRS. Raymond and Souques also reported a case of acromegaly of many years' standing, in a man, aged fifty-four, who in the last three years had developed Jacksonian epilepsy limited to the right upper extremity and right side of the face. They stated that the hypertrophy of the pituitary gland present in acromegaly constituted a cerebral tumor capable of exciting from a distance the cortical psychomotor centres.

Cord Lesions Produced by Microbic Toxins.—DR. H. CLAUDE, of Paris, had studied the cord lesions produced by microbial intoxication in four cases, as follows: 1, a guinea-pig, poisoned gradually by the toxins of the colon bacteria, became paralyzed in one foot, then in two feet; 2, a dog, poisoned by the toxins of diphtheria, in the course of a month, paresis of the hind feet; 3, a dog, poisoned by the toxins of tetanus (two months), posterior monoplegia, then paraplegia, finally paralysis of all the limbs; 4, a rabbit, poisoned by pyocyanic toxin, death without paralysis. Pathologically he found, besides gross vascular lesions, centres of softening and leucocytic infiltration; also cell alterations, varying with the degree and intensity of the intoxication and the part of the cord acted upon by the toxins. In the cases of slow intoxication there were all degrees of cell change in the cord, and, alongside elements still intact, there were others entirely degenerated. But cell alterations existed not alone in animals presenting nervous symptoms, but could be demonstrated by the method of Nissl before these symptoms made their appearance.

Acrocyanose.—DR. CROCQ, JR., of Brussels, said the syndrome to which he would apply the term acrocyanose was neither Raynaud's disease nor the blue œdema of Charcot, although it had some of the features common to these two affections. He had observed two typical cases in young hysterical females. The local cyanosis was constant; the pain was not intense; it did not cause gangrene, nor eruption, nor abolition of sensibility; nor was there, as in Charcot's blue œdema, either œdema, paralysis, or paresis. All three affections had, as a cause, disturbances of nervous centres, yet it seemed to Crocq that acrocyanosis was more especially a hysterical vasomotor phenomenon.

Unusual Duration of General Paralysis, Disappearance of its Special Symptoms, Termination in Simple Dementia.—DR. LAPOINTE said that general

paralysis might in some cases be of very long duration, and its cardinal symptoms disappear, to be replaced by those of dementia pure and simple. In one instance cited the duration was fifteen years.

Physical Insensibility.—DR. LAURENT, of Bordeaux, related a case illustrating the lack of susceptibility to physical pain in many of the natives of Indo-China, shown by their self-inflicted mutilation, suicide, etc.

Lesions of the Cord Cells Consecutive to Section of Nerves and Anæmia.—DRS. G. BALLET and JUTIL produced by experiments the same changes which were found in the cells of the cord in peripheral neuritis, their experiments consisting in division of the sciatic and in causing anæmia of the cord by compression of the aorta. The latter method showed the changes to best advantage: After rendering the animal paraplegic two or three times by repeated compression of the aorta, the lesions would be found more delicate and complex in the nerve cells, the cellule being rounded; the color granulations disappeared. Here as well as in section of a peripheral nerve there was melting of the protoplasmic granulations.

The Semeiology of Tremors.—Two reports were presented upon this subject—one by DR. LUCIEN LAMACQ, the other by DR. GRASSET. Both recognized the classical division into: 1, tremble of repose; 2, tremble in voluntary movement. Of the former, paralysis agitans was an example; of the latter, disseminated sclerosis. According to the number of vibrations one distinguished: 1, slow tremor, three to five oscillations a second—paralysis agitans, senile tremor; 2, medium, six to seven oscillations—disseminated sclerosis; 3, rapid or vibratory tremor, eight to nine oscillations—exophthalmic goitre, some cases of paralysis agitans. But certain tremors could not be thus classified, and others were polymorphous. Besides, Pitres had shown the frequent existence of tremor during the normal state, affecting different parts, including the hands, and here showing itself like the tremor of exophthalmic goitre—rapid oscillations of little amplitude. Grasset stated, in his *résumé*, that the semeiological value of tremors was variable, because there were a number of transition forms among the diverse types described, for certain forms were as yet imperfectly defined. In some cases the trembling was only a passing manifestation without great importance; while in others, when constantly present, it was of great significance.

Tremor and Rhythmic Spasm of Traumatic Origin.—DR. DELMAS related a case of tremor and rhythmic spasm with hysterical stigmata in a young man, and having apparently for cause a trauma five years back. He was cured in less than three months by hydrotherapy and bromides.

Physiological Tremor.—DR. PIERRE PARISOT stated that everybody trembled more or less when in normal health, as he and Meyer had found by test of the muscles when in a state of relaxation.

Tremor and Suggestion.—DR. BERNHEIM stated that hysterical trembling, at least if it were not constant, was always curable by suggestion. This was also true of hysterical chorea; but true chorea, that which was not due to imitation, resisted suggestion, although the amplitude of the movements could thus be reduced. Paramyoclonus multiplex responded to suggestion; also some cases of post-hemiplegic tremor. The trembling of alcoholism, saturnismus, paralysis agitans, and Basedow's disease was not curable by suggestion.

Tremor Accompanied by Cracking Sound.—DR. VOISIX had observed four women in whom a cracking sound proceeded from the upper part of the body, neck, shoulder, or trunk, loud enough to be heard at a distance of five or six steps. He assured himself that

the sound did not proceed from the articulations, but rather from the muscles, in which one could appreciate a tremor. Treatment by suggestion had no effect.

Tremor of the Tongue in Melancholia.—DR. PARANT said some melancholiacs showed tremor of the tongue; others did not. When present it was what he called voluntary titubation when the tongue was protruded, was seen in melancholia of recent date and infectious origin, and was a favorable sign in prognosis.

DR. RÉGIS said trembling of the tongue was not limited to melancholia of infectious origin, but was also present in infectious delirium, as in acute mania; and, therefore, could not be pronounced a sign of favorable prognosis.

Nystagmus by Suggestion.—DRS. SABRAZÈS and CABANNES had seen three cases of nystagmus in hysterics, in two being induced by hypnotic suggestion, in the other occurring spontaneously. It differed from the nystagmus of disseminated sclerosis. The oscillations of the eyes were extremely rapid, horizontal, associated, and exaggerated under strong light.

Commitment of the Insane.—DR. PAUL GARNIER, in a report on this subject, said that in the present state of our knowledge of psychiatry, isolation (from the general community) remained the best and most essential measure in most cases in the treatment of insanity. Its efficacy was greater the sooner it was carried out. The term dangerous could not be applied in the sense that some should be isolated and others allowed to be at liberty, for one knew not at what moment the apparently inoffensive might become dangerous. Besides, they needed hospital care, especially if indigent. The progress made in mental pathology tended to the almost complete suppression of physical restraint in asylums. Moral treatment, it seemed, could not rest on a system of intimidation by menace or actual punishment. Its principal value depended upon the word of authority of the doctor and affectionate display of benevolence, which many insane were still able to appreciate. Provisional discharge, although having inconveniences for the administration, also had certain advantages. The division of special institutions into asylums for treatment and into asylums for the incurable presented more inconveniences than advantages, and was not in accord with modern progress. But it was important to disencumber asylums of the feeble and senile, for whom there should be special hospitals, not necessarily under the law for the insane. The inmate of an asylum, when sent out cured, ought not to be abandoned to his own resources, but should be given work and receive the aid and affectionate oversight of public or private charity, as it might be required. The remainder of the conclusions related to the law of 1838. DR. Garnier thought there was room for an additional article relating to recurring deliriant alcoholics, of whose cure one could not be assured and against whom society could not effectually defend itself.

The chief dissension from the report related to the class of cases which should be committed to asylums, and division into curable and incurable.

DR. CHARPENTIER mentioned the following among those not necessary to be confined: Certain cases of attempted suicide; certain senile dement; lucid epileptics and hysterics; certain idiots; many imbeciles who were not dangerous; the backward who should be in educational institutions; many cases falling under the heads moral insanity, reasoning mania, hallucinatory alienation; recurring alcoholic delirians, who should be transformed into reasoning beings. Some of these persons required aid of one form or another, but need not be committed to insane asylums. He wished to see the asylums disencumbered of cases not properly belonging in them.

DR. TATY, of Lyons, believed in division of asylums into those for the curable and those for the incurable; and DR. MARIE thought the problem would be solved by dividing the cases into the acute and the chronic. About three-fourths of all were not benefited by therapeutics.

DR. PICHENOT presented a rare and curious specimen of hyperostosis of the cranium in an epileptic female.

Delirium of Persecution of Double Form.—DR. VALLON mentioned the fact that the insanity of persecution manifested itself in two forms, as a rule—reasoning and hallucinatory; but lately he had seen a case uniting the two forms. He would call it delirium of persecution of double form. Out of a large experience he had seen but one case.

Certain Psychical Troubles, Particularly Transformation of Personality, in the Course of Senile Dementia.—DR. PARISOT, of Nancy, said that psychical troubles independent of all insanity might appear during the course of senile dementia; and these troubles, such as the transformation of personality, deliriant conceptions, abnormal acts, were due to the revival of past psychical states under the influence of positive suggestion, spontaneous or provoked. They showed peculiarities which distinguished them from insanities.

Senile Dementia and Toxicity of the Urine.—DRS. PARISOT and LÉVY, of Nancy, having made some researches as to the relation between toxicity of the urine and senile dementia, gave the following brief *résumé*: 1. In one case of simple senile dementia (dementia without delirium) the urinary toxicity had varied in notable proportions, but without influencing the dementia. 2. In several cases of senile dementia with maniacal delirium, the appearance of delirium was always preceded by notable diminution of the urinary toxicity, a diminution which several times enabled them to foretell the delirious attack.

Automatic Speech.—DR. BERNHEIM presented a woman who was suffering from aphasia and paraphasia, but who, nevertheless, could sing and recite correctly her prayer. It seemed, therefore, that automatic speech was retained, while voluntary speech was much involved. Ordinary speech was attended in healthy subjects by a series of multiple transmissions cerebrally, which could not take place in the patient shown.

Neurasthenia and General Paralysis.—DR. RÉGIS said that these two affections might be associated, and they might resemble each other. Neurasthenia was to be distinguished from general paralysis by the fact that syphilis was a principal factor in general paralysis; also by the relatively greater age of neurasthenia and the fact that the speech disturbance was more emotional.

DR. CHARPENTIER had observed that when one pupil was more dilated than the other in general paralysis it was the right, whereas in healthy subjects it was the left.

DR. VALLON said he had not observed this difference, that the right pupil was oftener dilated than the left in general paralysis.

Case of Clinical Equivalent of Migraine.—DR. LAMACQ related the case of a patient who always suffered, the morning following a day of unusually severe labor or one in which he had experienced a disappointment, from either pain in the right foot or right hemisphericity. In either instance there would be nausea, difficulty in accomplishing mental work, etc.

Sulphate of Duboisine as a Means of Combating Refusal of Food in General Paralysis.—DR. FRANCOTTE had injected once or twice in twenty-four hours a solution of sulphate of duboisine, 4 to 1,000, as a means to induce patients with general paralysis to take food, and had found it successful in four cases.

Clinical Department.

A CASE OF RAYNAUD'S DISEASE.

By J. H. HAUPTMANN, M.D.,

ERIE, PA.

ON March 16, 1893, I was called in the afternoon to a woman in this city, Mrs. Z—, aged forty-seven years. On my arrival I found the patient sitting in a chair, suffering much pain in her legs and arms. She was much emaciated, her face was pinched, and she had all the appearance of one who had been long suffering. On examining her, I found both feet and legs very black, the discoloration gradually becoming less and shading off into the natural color at a point about two inches above the knees. The same condition was noted in her hands and in her arms up to a point about three inches above the elbows. Her nose and ears also had a dark hue. She had been in this condition for over four weeks, the discoloration gradually extending upward. She had during all this time suffered severe pains, accompanied with sleeplessness and entire loss of appetite. Her pulse was very feeble, intermittent, and somewhat thready, and her temperature was 102.5° F.

She had been under the care of several physicians, who had pronounced the case to be one of senile gangrene, and had advised immediate amputation. The family history was negative. Her parents and grandparents had died at an advanced age, and none with any hereditary or nervous disease. The patient herself had always worked very hard; she had borne seven children, all with hard labor, and had had one abortion, followed with puerperal septicaemia. Otherwise she had been healthy until this disease came upon her. Her heart was very weak and irregular.

After careful examination I made a diagnosis of Raynaud's disease, due to vasomotor contraction. The main difference between senile gangrene and Raynaud's disease, so far as local appearance is concerned, is that in senile gangrene there is a sharper line of demarcation between the diseased and the healthy parts, whereas in Raynaud's disease there is a gradual shading off from the dark color into the natural flesh color.

I went back again that evening and applied electricity, using the faradic current, to her legs and arms, for each extremity twenty minutes, changing the current from time to time. In bed, her limbs were elevated and massage was gently employed. That night she slept four hours, without any narcotic or anodyne being given. In the line of drugs I prescribed a nerve tonic of quinine, iron, arsenic, and strychnine; and for her weak circulation used digitalis, strophanthus, and nitroglycerin. Under this treatment and with nourishing food she quickly rallied.

After one week's treatment as above outlined, the natural color of her limbs and arms had reappeared as far as the toes and fingers, and these gradually resumed their natural color, and in three weeks' time she walked outdoors. The only parts that were dead were the first phalanges of all fingers, which later on I amputated and which soon healed nicely. She continued the treatment for several months longer, and has had no trouble since. She now follows up her occupation of sewing as usual. In the winter she is at times during the coldest days troubled with slight tingling and burning in the tips of her fingers, but the use of the battery always allays this; also rubbing the fingers will always stop it. I presume that without the use of occasional electricity and general hygiene, she might be liable to have another outbreak.

9 WEST ELEVENTH STREET.

A CASE OF ANTITOXIN POISONING.

BY L. ROSENBERG, M.D.,

NEW YORK.

LUCILLE J.—, aged four—previous history good, the child having been free from all illness up to the appearance of the present trouble—was taken sick on Sunday, July 5th, with sore throat and a rise of temperature to 101.5° F., per rectum. The heart, lungs, and kidneys were perfectly normal, and the little patient was well-nourished and well-developed for her years. On the 6th, the appearance of a small membrane on each tonsil warranted a clinical diagnosis of diphtheria (subsequently verified by culture), and she was given one injection of two thousand units of antitoxin. This was at about 1:30 P.M. She slumbered quietly for about an hour, when the mother (an unusually observant and intelligent woman) noted that the child appeared to become cyanosed. She awoke, complaining of cold, and was taken with a severe, prolonged chill; lapsed into unconsciousness and collapse. Physicians were hastily summoned, and Dr. Whitman H. White responded. He found the child, as he believed, *in extremis*. The temperature per rectum was 109° F., verified by myself when I arrived twenty minutes later. However, he gave the child one-one-hundredth grain of strychnine hypodermatically, and also two minims of digitalis fluid extract in ether. The pulse was scarcely perceptible when I took charge of the case. The patient was rigid, icily cold; the pupils were dilated to their utmost; a profuse perspiration appeared all over the body; a large quantity of coal-black faces was involuntarily expelled, resembling meconium but of darker hue and staining everything with which it came in contact. I concluded to supplement the other stimulants with nitroglycerin, one-fiftieth grain of which was injected under the skin. It was found necessary to repeat this in twenty minutes. The pulse rallied nicely from this, but the condition was extremely menacing. There was more or less rigidity, notably of the muscles of the neck; there was partial opisthotonos; the surface temperature continued frigid and the skin clammy. Hot-water bottles were placed all about the child. Four ounces of strong coffee, with two ounces of cognac, were thrown into the rectum, hot, and were retained. This was repeated in an hour. The nitroglycerin had to be exhibited freely and frequently, the heart action being extremely feeble and irregular. In all, the little patient received one-eighth grain between 3 and 8:30 P.M., when she began to rally. Although still unconscious, her pulse was slower, full, and regular; the normal bodily temperature obtained, the pupils were less widely dilated, the temperature was 103° F. per rectum. Nourishment could not be given; an enema of whiskey, milk, and egg was not retained.

This condition continued as described until midnight, when she came out of the stupor. Attempts were then made to nourish her with small doses of champagne and an infant food, but the stomach rejected everything. The vomit was fluid and inodorous, but contained the same dark coloring matter as the stool before described. The rigidity gave way to extreme restlessness, the patient writhing about in the bed, with very short intervals, during which opisthotonos would recur. Ten grains of sodium bromide were given per rectum, without benefit. The extreme nervous perturbation continued.

At 11 A.M., Tuesday, the temperature was 101° F.; the stomach was still rebellious. The child was fully conscious, but complained of nothing; the restlessness was unabated. A second rectal injection was given, containing ten grains each of sodium bromide and chloral hydrate, and two drachms of whiskey. The stomach was quieted by one-twelfth grain of mor-

phine, given hypodermatically. From now on the condition became more tranquil, the child slumbering, though fitfully. The stomach retained small doses of fluid nourishment; the temperature fluctuated between 101° and 102° F. during the day.

Wednesday morning the temperature, pulse, and general condition were as nearly normal as could be expected under the circumstances. The membrane had entirely disappeared. The first urine obtained (twenty hours after the onset of the collapse) was foul smelling and strongly alkaline, but free from albumin or blood. The subsequent history was uneventful, and at this writing the child is as well as ever. The small quantity of iron which the child received before the antitoxin was resorted to was insufficient to give the stool the deep black color it presented. The dark color of the vomit is also unexplainable. The condition of the digestive tract had been normal prior to the illness. Elsie, an older sister, had been given three hundred units of antitoxin from the same source, without any untoward symptoms developing. The injections were made by one of the most experienced physicians on the staff of the health board.

210 EAST ONE HUNDRED AND TWELFTH STREET.

A FISHHOOK REMOVED FROM AN INFANT'S THROAT BY DIGITAL MANIPULATION.

BY THOMAS B. HEGEMAN, M.D.,

BROOKLYN, N. Y.

ON August 21st an infant girl, two years old, was brought to my office by the mother, who stated that the child had "swallowed a fishhook."

On examination I found that about one inch of the catgut to which the hook was attached was protruding from the mouth. Placing a wine-bottle cork between the upper and lower molar teeth of the right side, I found on inspection that the fishhook had passed into the throat and had been carried to the lower part of the pharynx, the point being embedded in the mucous membrane of the lateral wall of the pharynx in the hyoid space of the left side.

Using the protruding catgut as a guide, the thumb and index finger of the right hand was passed along into the pharynx. The end of the shank of the fishhook could then be felt, but only about one-fourth inch of the shank could be grasped by the fingers. Securing as firm a grasp as possible on this small lever, I passed the index finger of the left hand deeply into the pharynx, until the point of the fishhook could be felt through the mucous membrane.

Realizing that the peculiar nature of the foreign body made it hazardous to either push or pull, I decided to try rotation. Giving the shank a quick twist the point of the hook was forced out of the membrane and caught in the skin of the index finger of my left hand. Having the hook now between the index fingers, it was an easy matter to withdraw it. There was very little laceration of tissues, and the operation took less than three minutes to accomplish. The hook was of the variety known as a "porgie" hook, about one and one-fourth inches long, with about six inches of catgut attached.

The case is interesting because of the nature of the foreign body. Many strange and curious things have been swallowed by children, but one does not often hear of a fishhook as a foreign body in the human throat. The case is instructive in showing how much can be accomplished by careful digital manipulation in removing foreign bodies from the throat.

363 NEWKIRK AVENUE.

APPENDICITIS COMPLICATING PREGNANCY.

By HOWARD CRUTCHER, M.D.,

CHICAGO.

At ten o'clock on the evening of August 1st, I was called by Dr. Frank H. Waters to see with him a young woman, aged seventeen, unmarried, American, who presented the following history:

On July 16th she was taken sick with cramps and pains in the stomach and bowels. There was some vomiting and the bowels were constipated. Two days later (July 18th) a two months' fetus was expelled. This development was a total surprise to the family, who at once called a neighboring practitioner to attend the case, until Dr. Waters could be called from the city. Dr. Waters and the other attendant held a consultation within a few hours after the expulsion of the fetus, and decided to curette and pack the uterus. This was done at once. The girl strongly denied any criminal procedures, and attributed the mishap to overexertion at the washtub. The condition, however, did not improve. Abdominal pains, constipation, and headache continued. The pulse rose quite steadily from day to day, and it was evident that general sepsis had developed.

I found the patient slightly delirious at times; the pulse was 160, with a temperature of 102.5° F.; the abdomen was not painful to pressure, although it was much distended. The uterus was explored carefully, but no traces of degenerated tissue could be detected at any point. The odor was quite offensive. There was hardly any discharge from the uterus. On account of the entire absence of pain, it was evident that she was already anæsthetic from sepsis. The bowels were discharging a dark, soft mass about every two hours, and had been very loose for three days. Previously to this, constipation had been very obstinate. The urine appeared to be normal in quantity and but slightly altered in quality.

My belief was that the patient was suffering from septic metritis. It was thought that a tubal complication might account for the peritonitis, although nothing in the patient's history justified such a belief. The patient's condition being utterly hopeless as she was, it was decided that an attempt at relief would be justifiable.

On account of apparent improvement during the night, the family insisted upon delay. This action put off the operation until the morning of August 3d. Chloroform was given by Dr. Waters. Assisted by Drs. F. H. Lockwood and A. S. Pease, I opened the abdomen in the median line three inches below the navel. On incising the peritoneum there was a hissing of gas, which, of course, led to the belief that an intestine had been opened. This was not so. In an instant there was a torrent of foul pus, which amounted to more than a gallon. The well-known wall of lymph, so eloquently described from time to time, had pushed the intestines and omentum up to within an inch of the umbilicus. At this time the prostration of the patient was extreme, but irrigation with gallons of hot saline solution revived her. The abscess cavity was enormous. Its walls were not broken at any point. Attached to the right tube and uterine fundus were the remains of a perforated vermiform appendix. It was strongly attached and no effort was made to remove it. After the use of many gallons of hot salt water, the cavity was quickly sponged and a large Mikulicz drain inserted.

The patient died in three hours, after apparent recovery from the shock of operation. Drs. D. H. Galloway, A. S. Pease, and the writer conducted an autopsy seven hours after death. Intestinal adhesions,

while recent, were universal. The liver was entirely adherent. The omentum was a friable mass, occupying the left lumbar region. The uterus and ovaries, aside from their recent coverings of lymph, were in apparently good condition, barring the usual congestion of the uterine tissues. The right Fallopian tube was normal, save at the point of attachment to the vermiform appendix, where a small collection of pus was found. The vermiform appendix was four inches long, and gangrenous for an inch where it was adherent to the tube.

In the absence of any other cause for the miscarriage, it is evident that the appendicular lesion was responsible for the trouble. Probably a former attack of appendicitis had been "cured" by the appendix attaching itself to the uterus and tube, where it held in store a magazine of infection, which, when released by the normal enlargement of the uterus, dealt the patient a swift and fatal blow.

103 STATE STREET.

A CASE OF OXALIC-ACID POISONING.

By PAUL W. ERDTMANN, M.D.,

NEW YORK.

MR. L—— called at my office in great excitement, and asked me to come with him at once, his wife having "taken something by mistake." I hurried to his home, and on arrival found his wife, a woman, thirty-five years old. She was in bed, vomiting bloody mucus. The respiration was short and jerky, the pulse small and irregular, the surface of the body was livid, and the skin was cold. She complained of severe abdominal pain and burning in the throat. I asked her what she had taken. She said in a whisper and very slowly that she had, by mistake, taken a drink from a bottle in which she kept a solution to clean the boiler with. She had mistaken the bottle for one containing lemonade which she had placed next to it. The husband told me it was oxalic acid. I did not scrape the ceiling, because a drugstore was opposite, to which I hurried the husband to get lime water. By this time the patient was almost completely unconscious and was cyanosed about the face. She had no convulsions. Vomiting had entirely ceased. I administered the lime water freely, and then gave mustard water, which, however, did not cause vomiting. I then administered apomorphine hypodermically. This promptly acted. The heart was stimulated all the time.

After two hours the patient was out of immediate danger and was perfectly conscious. She then told me she had dissolved an ounce of the acid the day before in a tumbler of water. She drank the whole amount. I suspected her of suicidal attempt, which, however, she emphatically denied.

The patient was also six months pregnant. On examination I could not hear the fetal heart sounds and quickening had ceased. I concluded the fetus was dead.

Next morning the patient was doing well: the pulse was good, the temperature was 102° F. The gastroenteritis was quite severe. Examination revealed that the fetus was dead.

Next morning I produced premature labor, introducing a carbolized-sponge tent, and in the evening the entire ovum, membranes, placenta, and fetus were discharged at one time. The patient made a complete, uninterrupted, rapid recovery.

I report this case, as there are but few instances on record of recoveries after the ingestion of an ounce of oxalic acid. Some writers have claimed that oxalic acid is an emmenagogue. In this case no uterine contractions were produced.

A CASE OF MALIGNANT DIPHTHERIA TREATED BY ANTITOXIN—RAPID RECOVERY.

BY ARTHUR IRVING BOYER, M.D.,

NEW HAVEN, CONN.

At the present time there seems to be so much doubt existing in the minds of many of the profession regarding the efficacy of antitoxin in the treatment of diphtheria, that some are no doubt deterred from even trying it for fear of failure. The case I am about to relate is one which came up in my own practice very recently. Saturday, July 25th, about 9:30 P.M., I was called to see the patient, a girl, eleven years old. I found her in a semi-comatose condition. Pulse, 120; respiration, 24; temperature, 104° F. Her father said that she appeared perfectly well Friday night and partook of a hearty supper; she slept well until about midnight, when she became a little restless, but did not complain of her throat or manifest any other symptoms at that time. Indeed, Saturday morning she was about the house; as the day advanced, however, she began to act drowsy, and then (about 5 P.M.) for the first time complained of a sore throat. Her father looked at her throat and told me that at that time all he could see was a "small white spot" on one tonsil.

As the child had had tonsillitis before, he did not attach very grave importance to it; but as she continued to get worse he sent for me. Upon examination of her throat I found both tonsils and the pharynx covered by membrane, parts of which had become necrotic. There was no room for doubt as to diagnosis. At 11:15 P.M. five cubic centimetres of antitoxin were injected (New York Board of Health No. 2). At this time her pulse was 120; respiration, 26; temperature, 104° F.

Sunday, at 11:15 A.M., another five cubic centimetres were injected. Both these injections were followed by marked reaction in about ten hours. At 11:15 P.M. there seemed to be a change for the better; she had a coughing-spell, accompanied by vomiting, and a small portion of the membrane became detached. At this time her pulse was 104; respiration, 20; temperature, 101.1° F; and she was conscious and rational.

Monday, at 10 A.M., another injection of antitoxin, this time two cubic centimetres, was given. Pulse, 100; respiration, 20; temperature, 101° F. At 8:15 P.M. I removed a piece of membrane as large as a fifty-cent piece, with long forceps. At 10 P.M. there was a reaction from the antitoxin given in the morning, and she was somewhat delirious.

Tuesday, at 10:10 A.M., I removed another piece of membrane with forceps. Pulse, 100; respiration, 20; temperature, 99° F.

Wednesday, 10:15 A.M., pulse, 100; respiration, 18; temperature, 98.5° F. She had slept from 11 P.M. to 5 A.M., and awoke very much refreshed. The membrane gradually disappeared. At 8:15 P.M. the pulse had fallen to 80; respiration, 18; and temperature, 98.5° F.; and they have remained so ever since.

The patient gained strength rapidly, and at the present time of writing, August 5th, she is out of doors, and her throat is in an entirely normal condition. Quarantine was raised yesterday.

I have seen a statement to the effect that "bacteriological" and "clinical" diphtheria are not closely allied. All I can say regarding this is that the diagnosis was proved beyond question by the finding of the Klebs-Loeffler bacillus, and the case from a clinical standpoint gave no reason for doubt, as, besides the throat symptoms, there was marked evidence of systemic infection which the temperature alone would not account for. No other treatment whatever was resorted to,

with the exception of drachm-doses of brandy in milk and an antiseptic mouth wash of boric acid in distilled water.

121 GRAND AVENUE.

A CASE OF COLLAPSE FROM EXCESSIVE VOMITING SUCCESSFULLY TREATED BY INTRAVENOUS INFUSION OF SALINE SOLUTION.

BY CARLOS C. BOOTH, M.D.,

YOUNGSTOWN, OHIO.

MR. CHARLES B——, aged twenty-six, millman, became suddenly sick with severe pain, accompanied by general cramps and vomiting of large quantities of fluid, at 2 P.M., July 28, 1896, while at work in the rolling mill. I attended him at 5 P.M., administering a large hypodermic injection of morphine, and repeated the same at 8 P.M. He continued vomiting large quantities of rice-water-like fluid during the night, but with less frequency.

On July 29th, although he had received large hypodermic injections all this time at intervals of two or three hours, the vomiting continued.

July 30th, at 9 A.M., he was still vomiting and from the excessive loss of fluid was rapidly approaching death. I gave him nitroglycerin and strychnine. The pulse was then 130 to 140; temperature, 96° F.: the eyes were sunken, extremities cold, and the man was vomiting occasionally. At noon Dr. J. Wilson was called in consultation, and we both agreed that if something radical was not done, death would surely follow, as the man was rapidly getting worse. At 5 P.M. the pulse was 160; temperature, 96° F. At this hour, assisted by Drs. Wilson and B. F. Hawn, I infused two quarts of sterilized normal saline solution, at about 120° F., into his right median basilic vein. The patient was throwing himself from one side of the bed to the other, as one dying from hemorrhage. Almost immediately he became warmer, fell asleep for a few moments, and the pulse from a flutter came down to 110 per minute, with a full volume. The man expressed himself as feeling much better and warmer; his extremities became warm, he perspired a little, and at once his condition improved in every way.

During the next twenty-four hours he vomited only three or four times. I continued the nitroglycerin and strychnine, and on August 1st he had a pulse of 96 per minute, normal temperature, desired food, and is at this time, August 7th, sitting up and feeling quite himself. There was no secretion of urine from July 28th to 31st, and no movement of the bowels until August 1st, and, in fact, I could obtain none previously to this time. It is not necessary to detail the minutiae of the treatment further than this, as we had used about everything that has ever been suggested for such a condition. In our opinion, this man would have died if he had not had the infusion. If occasion presents itself, I shall not hesitate to recommend and use this treatment in the above condition, regardless of the age of my patient.

Vinegar as an Antidote to Carbolic Acid.—Professor Carleton (*La Semaine Médicale*) says that when applied to a skin or mucous membrane burnt by carbolic acid vinegar causes a quick disappearance of the characteristic whiteness, as well as the anæsthesia produced by carbolic acid; and prevents the formation of a slough. It also neutralizes any carbolic acid that may have been introduced into the stomach. In cases of poisoning, then, the first thing to do is to make the patient drink some vinegar mixed with equal parts of water, and to wash out the stomach. According to Billroth, soap is an antidote in carbolic-acid poisoning.

Therapeutic Hints.

Turpentine is said to be a specific for parotitis.

Antihysteriæ.—It is said that one-tenth grain of apomorphine given hypodermatically will break up and thereafter prevent any attack of hysterics.

M. Dose: A dessertspoonful or more twice daily.

—Gaz. hebdomadaire de Méd. et de Chir., 1896, No. 19.

Chancroid.—Cleanse and dry the parts. Apply salicylic acid so as to cover the ulcer and a narrow zone of skin beyond. Cover with an adhesive plaster. Dress every twenty-four hours. On the third day replace by an ointment. Three days after falling of the eschar reparation is complete.—HEBRA.

Bronchitis of the Aged.—

R Benzoic acid gr. ivss.
Tannic acid. gr. ii¼.
M. For one cachet. S. Take four or five such cachets per diem.

—E. MARAGLIANO, *Le Progrès Médical*.

Heart Failure in Phthisis.—But one of the most serviceable means, which has stood me in very good stead, is taking advantage of the physiological relation between the act of swallowing and the act of expectoration. Repeatedly we see in adults with phthisis the benefit of sipping hot fluids to ease their morning expectoration. The experiments of Kronecker and Meltzer prove that this result comes about mainly by stimulation of the heart with each act of deglutition.—DR. THOMSON, before the Academy of Medicine, April 7, 1896.

Infant Feeding.—Dr. Dillon Brown (*American Medical and Surgical Bulletin*, May 9, 1896) says that the farinaceous foods and the so-called milk foods are, in his experience, rarely or never indicated, and are usually harmful. In children with poor digestive powers, the Liebig foods are often of value; but they never can be and it never has been claimed that they are substitutes for milk, and are only to be used as a valuable addition, in certain cases, to properly handled and properly modified cow's milk.

Typhoid.—Dr. Henshaw (*Boston Medical and Surgical Journal*, May 14, 1896) commences an article as follows: "Within the last few years, more than fifteen hundred remedies have been suggested for the treatment and cure of typhoid fever. All sorts and kinds of foods have been advocated as of special value in the diet; hydrotherapy and antipyretics have been advised for the reduction of the fever; attention has been called to the value of intestinal antisepsis; while the special symptoms arising during the course of the disease have been relieved, experimentally at least, by almost every resource of the pharmacopœia. These methods, however, have not proved invariably efficient in modifying the course or severity of the disease."

Foreign Bodies in Ears.—Dr. Belt (*Virginia Medical Semi-Monthly*, April 24, 1896) gives this important admonition to the general practitioner: The physician is frequently called upon to remove foreign bodies from the ear—such as insects, grains of wheat, corn, beans, slate pencils, etc. Sweet oil or glycerin will usually kill or quiet an insect, after which it can be removed as any other foreign body—that is, by means of a syringe and warm water. Never use a probe, ear-spoon, or forceps in these cases, as great injury may be done while contending with a struggling child. Foreign bodies sometimes remain in the ears for years without doing injury, so there is no need of haste, excitement, or forcible methods in dealing with them.

Chills in Typhoid Fever.—Dr. Osler, in the *University Medical Magazine*, November, 1895, says chill may occur—First, at the onset of the disease, as seen in thirteen cases out of a total of seventy-nine treated at the Johns Hopkins Hospital during the sixth year. Second, at the onset of the relapse, due to an irregular or a disturbed elimination of the poison, a large volume of which is thrown into the blood in a short time. Third, as a result of treatment, antipyretics being

particularly prone to produce chill, and this phenomenon may occur after the injection of sterile cultures of bacilli and after the external application of guaiacol. Fourth, with the onset of complications, such as pneumonia, pleurisy, acute otitis, suppuration in the mesenteric veins, pyemic abscesses of the kidney, perforation of the ileum or appendix, or an acute peritonitis. It may occur with thrombosis of the femoral or saphenous veins, and it may precede acute and fatal hyperpyrexia. Fifth, during convalescence in severe and protracted cases. In such cases there may be no local symptoms to account for the chills, and, though alarming, they may gradually subside, with complete recovery. They may possibly be septic. Sixth, chills may be due to concurrent malaria. While attributed, as a rule, to malaria, chills in the course of typhoid fever are very rarely due to this cause.

—DR. BROWN, *Va. Med. Semi-Monthly*.

Enuresis in Children.—Dr. Harold Williams (*Boston Medical and Surgical Journal*) gives statistics of sixty-two cases: twenty-eight in boys, thirty-four in girls, of ages from two to fifteen. In thirteen cases definite causes of reflex irritation were discovered, with prompt cure of the enuresis in twelve cases. These causes were: Adherent prepuce, four cases; vulvo-vaginitis with gonococci, one case; oxyuris vermicularis, five cases; chronic ileo-colitis, one case; prolapse of the rectum, one case. Anæmia and a neurotic temperament and history were present in most of the cases. Forty-nine cases remained unexplained.

Causes of Migraine.—Dr. Marcus, of Pymont, has suffered from periodic headaches for forty years and thinks they are due to changes in the atmospheric pressure. He finds that the advent of his own attacks and of those of others are always coincident with a variation in the pressure, which is not always accompanied with a change in weather, but is confirmed next day by the official weather bulletin. Dr. Marcus asks physicians who live in localities where the atmospheric pressure is more stable to investigate the matter and possibly find some relief for chronic sufferers. —*Therapeutische Wochenschrift*, March 29th.

Local Anesthesia in Labor.—Dr. T. H. Weagly (*Times and Register*, October 5, 1895) has obtained excellent results in cases of rigidity of the cervix by local anæsthetics applied to the parts by a spray apparatus. He claims that the following solution will expedite and soothe the first stage of labor, and even when the occiput has entered deeply into the pelvis the pain accompanying the expulsion of the head may be reduced to a minimum by spraying the vaginal surface of the perineum and outlet.

M.

Fevers.—Dr. Da Costa, in the *American Journal of the Medical Sciences*, June, 1896, says: "The treatment of the prolonged simple continued fevers is purely symptomatic. Quinine has no effect on them, nor have the ordinary antipyretics more than a temporary influence. Phenacetin and salol do most good, partic-

ularly in cases with headache. They are best given in small doses, a grain or two, frequently repeated until their effect is manifest. Better still, when it can be efficiently carried out, is the cold-bath treatment, not only to lower temperature but for its revulsive and alterative influence. I regret that in the extremely long cases first mentioned circumstances prevented it from being thoroughly carried out. Purgatives, unless contraindicated by weakness, always form part of judicious treatment."

Syphilitic Brain Disease.—1. In syphilis of the brain, especially of the meninges, severe headache is an early, often predominating, symptom. In our case the patient did not suffer from headache of any consequence till partial paralysis had developed, nor was his headache at any time more severe at night, as is often the case in specific disease. 2. The course of syphilitic brain disease is subject to great variations in the intensity of the symptoms; sometimes from day to day, or week to week, symptoms come and go and do not show the steady development observed in the case under question. 3. Specific meningo-encephalitis yields readily to energetic specific treatment, especially when applied early. Our patient grew steadily worse under a thorough course of specific treatment; nor were there any other signs of syphilis of the nervous system, as is so often the case, present to support the diagnosis of syphilis.—DRS. STIEGLITZ, GERS-TER, LILIEN-THAL, *American Journal of the Medical Sciences*, May, 1896.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GENERAL MEDICAL COUNCIL—CANDIDATES—RETI-
RING MEMBERS—COLCHESTER MEDICAL SOCIETY—DEFENCE
UNION—"BALDERDASH" AS INTERPRETED BY BRU-
DENELL CARTER AND VICTOR HORSLEY—INDIRECT
REPRESENTATION REVIVED—DANGEROUS TRADES
REPORT—PETROLEUM REPORT—SANITARY CONGRESS
—ARMY VACANCIES.

LONDON, September 4, 1896.

THE medical council, though not sitting, is monopolizing the attention of many medical politicians. First, the coming election of direct representatives gives rise to discussion of the claims of the candidates, and fresh names are continually being suggested. I should think some of the gentlemen whose names have been mentioned by their friends or others would have preferred to keep the proposal out of print. I shall not call them candidates until they declare themselves such. Among those who have done so, Dr. Rentoul will be remembered as the man who defeated the midwives bill by his indomitable courage and energy, and at no little pecuniary sacrifice. This is certainly no little claim. As one of the retiring members, Sir W. Foster, is an Irishman, some of our delightful Hibernian colleagues have suggested that the occasion should be seized for doing justice to Ireland by sending two of her sons to replace him; and this Hibernicism has actually drawn a refutation from a sober writer, who thinks it is time England should be considered at the election of three members for England. The qualifications for the office do not seem to concern many, and so we see such claims as these put forward, as well as others which have equally little bearing on the duties of councillors.

At Carlisle the British Medical Association assumed to thank Mr. Wheelhouse and Sir W. Foster for their services, and an effort was made to beg them to con-

tinue. This is in accordance with their election at first, which was managed by the committee of the association, of which these two gentlemen were members at the time. It is the fashion within the inner circle of the association to extol the work of these two members in the council, and to hold them up as model direct representatives. Outside we smile at the advertisements that proceed from within, and admit that they were direct representatives of the inner circle. When it is asked what they have done, an answer is seldom given, though occasionally we are told they voted for an increase in the number of direct representatives. Really, a great deal too much has been made of their so-called services, and now it has been proposed to get up a testimonial to them for doing the duty they sought so ardently. I hope no one will be hoodwinked into subscribing. They secured the position by electioneering tactics of the lowest order, and if they have voted as directed by the clique who manœuvred the election, let their retirement close the disgraceful page of the history.

The Colchester Medical Society has nominated Drs. Rentoul, Drage, and George Brown as candidates. Some other societies are proposing candidates, or, rather, selecting those they intend to support. The attempt of the British Association through the Lancashire and Yorkshire branch is thus being followed, but that attempt has led to an unpleasant dispute as to whether its nomination was in order. I am afraid there is something in the objection raised to the proceeding, but it will not invalidate the election, being only a resolution of a small meeting to support certain candidates—a meeting held for another purpose, viz., to hear an address by Prof. Victor Horsley. I am sorry he should have been mixed up in this move on behalf of those he supports. He is president of the Medical Defence Union, which in its brief career has done more for the interests of the profession than the General Medical Council in its thirty-seven years of talking and passing recommendations. Mr. Horsley's surgical fame has long since reached you, but you may not be aware that he has developed equal skill and energy in the task he has undertaken as president of the union. I hope he will retain that office and work it as he has done hitherto. The decision of the British Association to take up medical defence does not necessitate any particular plan. I am half-disposed to believe the safest for the time being would be to vote funds for every case undertaken by the union, up to a fixed limit in the year or for each case. This would give the union a free hand, and Mr. Horsley and those working with him would be encouraged to continue to give their great experience and talent to the work they have done so well, and for which they only need further funds.

Mr. Horsley has also come out as an acute dialectician. I told you Mr. Brudenell Carter, a keen controversialist and experienced journalist, had written to *The Lancet* a defence of the Medical Council from the criticisms to which it was subjected at Carlisle. Mr. Horsley read a paper there, as did the candidates he supports. They treated the defects of the council from different points of view, and Mr. Carter called their statements "balderdash," which he subsequently pronounced to be "a good old English word, meaning a confused statement." Mr. Horsley is equal to the occasion, and quotes authority to show that though in early Scandinavian it meant so, it gradually came to be applied to the sayings and arguments of persons who talked nonsense, and its present-day synonyms, according to the great authority of Roget, are "nonsense, jargon, gibberish, jabber, babble, hocuspocus, fustian, rant, bombast, rigmarole, twaddle, fudge, trash;" and, he adds, it also appears that balderdash means, further, "a tale told by an idiot, full

of sound and fury, signifying nothing." These are hard words, Mr. Horsley thinks, though after Mr. Carter's "graceful explanation" he is happy to know that they were not intended to apply to the criticisms of the council made at Carlisle. This is the lively part of the little discussion Mr. Carter provoked. There is plenty more and of a serious kind, demonstrating that Mr. Horsley knows what he is talking about, and that his trenchant criticisms of the council are founded on a basis which has not been shaken.

In the discussion at Carlisle on the subject, the most interesting point was the revival by one speaker (Dr. Muir) of the question of indirect representation as preferable to direct. How should more influence be obtained? Instead of more direct representatives to enlarge the council, he held that every diplomat of a corporation or university ought to have a vote in the choice of a representative of such body on the council. Some dissentients to this were present, as might be expected, but it is clear that such a reform would be popular and effective. It was advocated with no little energy some years ago, and the association made a great blunder in opposing to it direct representatives in the hope of controlling the elections.

A year ago the home secretary appointed a committee to inquire into dangerous trades. After inspecting one hundred and thirty-four works and examining one hundred and fifty-three witnesses, the committee has presented an interim report, in which a number of recommendations and suggestions are offered, with a view of protecting the health of workpeople without pressing too heavily on employers or adding to the difficulties of keen competition. Most of the recommendations are already in use in the best-regulated works, where employers regard their workpeople with interest, and it could, therefore, be no hardship to make them compulsory on any who may have no thought for the health and welfare of those who contribute to their own prosperity. The dangers to life and health in various occupations may, perhaps, be minimized by judicious legislation, and careful inquiries such as this are the best preparation for parliamentary action.

The select committee appointed to inquire into the laws relating to the keeping, selling, using, and conveying of petroleum and other inflammable liquids, being unable to conclude their inquiries in the parliamentary session, reported the evidence they had taken and recommended the house to reappoint a committee next session. This will probably be done. Meantime, it may be observed that there were great differences of opinion among the witnesses examined, especially as to the existence of a safety-flash point for paraffin. The alternative of looking to the construction of the lamps presents itself. I suppose that we must await next session's committee for further investigation and legislation, but as there are safety lamps in the market prudent people will decline to purchase others.

On Wednesday the Duke of Cambridge opened the congress of the Sanitary Institute at Newcastle-on-Tyne, and judging from the proceedings of the two days that have elapsed, the meeting promises to be successful.

Competition in the army medical service is dead. At the last examination, as I reported, only thirteen were passed, and for them twenty-five vacancies waited. But a further need has occurred from resignations, and there are twenty-two places waiting for qualified candidates; but none of these are coming forward. The "combatant officers" have killed competition, and will yet feel the want of skilled surgeons.

Obesity.—Duboisine is said to cause persistent loss of flesh.

A PROPOSED CONGRESS OF LEPROLOGISTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Goldschmidt, late of Madeira, now at Paris, in a letter to me, last December, proposed that a congress of leprologists should be held, for the suppression and prevention of leprosy. In a letter I wrote to Dr. Hansen, I referred to this proposition and suggested the formation of an international committee, one delegate from each government, to be permanently active, to meet once a year, and to take cognizance of all questions and problems relating to leprosy all over the world. I also suggested the collection of a fund in every country, for the use of this committee, to support asylums where such help is wanted, and to send specialists wherever they are needed. Dr. Hansen at once received these overtures with favor, and submitted them to his chief, who in turn communicated them to the Norwegian government. In his answer to me, Dr. Hansen said that it was the desire of the Norwegian physicians that the seat of the first leprosy congress should be Bergen, Norway, and that the Norwegian government was willing to issue the call for the first leprosy congress, provided it had assurances of sympathy from other governments. I at once applied to President Cleveland, to Queen Victoria, to the German Emperor, to President Diaz of Mexico, to Lord Aberdeen of Canada, to the Japanese and Chinese governments, and to all the republics of South America. I also submitted this scheme to the American Dermatological Association, to the American Public Health Association (of Canada, the United States, and Mexico), and to Miss Clara Barton, the president of the American Red Cross Society. It is to be communicated also to the Pope, through a hierarchical channel. It is desired that every influence that may exist, of any kind, be brought to bear upon the different governments, so that they may consent to appoint official delegates. Of course, leprologists in their private capacity, or as representatives of associations, will be invited and are expected to attend. The committee formed by the delegates will be exclusively concerned with the promulgation and application of laws suitable to the suppression and prevention of leprosy in each country, leaving the discussion of questions of etiology, bacteriology, cure, etc., to the specialists. This is the plan as it stands now, and as it was resubmitted by me to Dr. Goldschmidt. Dr. Goldschmidt, in his reply, has suggested that Moscow be the seat of the congress, as the international congress is to meet there next year. This is open to the following objections: 1st, If the leprosy congress is held in Moscow, along with the regular international congress, it will of necessity fall into position of secondary influence, and will be, in fact, a section of the general congress; 2d, Hansen is entitled to claim the first leprosy congress, he being the discoverer of the *lepra bacillus*; 3d, the Norwegian government, having been the first to express a willingness to issue the call (which should be issued by a government, not by individuals), is entitled to the honor; 4th, if the congress is now taken to Moscow, after the Norwegian physicians have expressed a desire to have it in Norway before even Moscow was suggested, the Norwegian physicians will certainly take offence. A leprosy congress without Hansen cannot well be imagined.

Will you kindly publish this letter, and ask the leprologists of America to communicate to the provisional committee of the congress as it exists—Dr. G. Armauer Hansen, Bergen, Norway; Dr. Jules Goldschmidt, 4 Rue Daunau, Paris, France; Dr. Albert S. Ashmead, 210 West Fourth Street, New York—their own ideas about this great scheme, and to offer such suggestions

as may help to advance it? May we hope, also, that you will use the influence of your paper to make the first leprosy congress a success?

ALBERT S. ASHMEAD, M.D.

THE APPENDICITIS CONTROVERSY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Readers of the MEDICAL RECORD who have been following the interesting discussion on appendicitis which Dr. MacArtney's article has elicited have at times felt that the personal element has been very manifest in most of the letters. It is unfortunate that calm discussion has been invaded by satire and often by sneers, which do not conduce to convincing argumentation nor show proper respect for the opinions of others. Dogmatic assertion on the one hand and ridicule on both are not calculated to allow a proper estimate to be made, or to favor the acceptance of observations that should be weighed in the balance of sober deliberations. Certainly all are entitled to express without fear or favor honest opinions and convictions gathered from personal experience. Very many readers of current medical literature are country general practitioners, who have not the advantages of hospital practice. There are bright and keen intellects among this large army of patient, hard-working men, yet how many keep in touch with the advances in thought and practice that master minds are developing along the lines of evolution in medical science in the centres of learning and research?

Are not aseptic and antiseptic principles defied by the methods universally in vogue everywhere in the management of all kinds of wounds—not excepting the puerperal uterus? The men who are constantly combating these "old ruts" and gallantly fighting against prejudice, ignorance, and often laziness are the very teachers to whom I, as a general practitioner, am looking for light in the darkness.

Is it not dangerous for us to accept and practise—to say nothing of advocating—plans of treatment which do not lower mortality and give incomplete results and tedious convalescence? We should have the courage of our convictions. All seekers after truth want to know, and should adopt, the best plans of treatment in appendicitis—the safest, shortest, and positively curative methods; those which ensure not simply a recovery (?) but a cure.

What we want is the cumulative evidence of, say, a thousand cases treated in and out of hospital by surgeons and physicians, their complete histories, embodying all the points that have a bearing upon their cases in any particular, before and for years subsequent to treatment; the sequelæ, complications, accounts of autopsies, and pathological reports. All theories based upon individual impressions from treatment should be eliminated, such as that opium favors adhesions or that colon irrigations absolve the sins of the *bacillus coli communis*. Perhaps then some rational and more uniform lines will be generally accepted as bases in treatment than seem to be followed at present.

I have had six cases that were reported in the *Buffalo Medical Journal* for February, 1896; also a few since, but I will speak here only of these six. My first case, that of a boy of six years, was treated against my judgment by the opium plan. I had but recently located, coming from a general hospital, and was unknown, while my *confrères* were men of established reputation and experience, who independently diagnosed the case as one of peritonitis and advised the opium treatment. The boy died in a few days of unmistakable septic peritonitis.

My second case was that of a man of fifty, who gave a history of a number of previous attacks. Surgical aid was deferred for about forty hours, and when the abdomen was opened the appendix had perforated in three places and was gangrenous, and diffuse peritonitis existed without any evidence of recent adhesions limiting the infective process. The man died. My third case was that of a young man, who also had had previous attacks; he was promptly operated on, and although the appendix was severed by perforation from a concretion and a large abscess was present without any adhesions, and pelvic peritonitis existed, yet the man recovered satisfactorily. The remaining cases—in two of which there had been several attacks—were treated medically. One was on the eve of being operated on, when the abscess discharged through the rectum. These cases terminated in recovery from the attacks, but the patients were not cured, as all complained for over a year afterward of pain and discomfort in the right iliac region on exertion.

Only the operated case made a satisfactory recovery, and is to-day free from the dreaded ventral hernia. I am not particularly proud of this as exemplifying medical treatment. I have added this experience of my own to confirm a conviction indelibly impressed on my mind—that operation done early is free from danger and gives a complete and speedy recovery as compared with medical treatment, which encompasses the patient with greater dangers. No one can say the cure is absolute, for often the system is left to struggle against a septic infecting focus and there is always a dynamite mine ready to explode at an inconvenient season. It is questionable whether opium favors the formation of adhesions or that, if it does, relapses are therefore less frequent; on the contrary, constricting bands favor relapse, and the patient has a false hope of cure.

S. W. S. TOMS, M.D.

BELLPORT, L. I.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is to be regretted that some of the readers of my former reply to Dr. MacArtney discovered any "keen sarcasm" therein, for it was my intention to take only a plain part in a plain discussion, which had for its object the determination of a scientific point. Dr. MacArtney is voicing the opinion of many responsible practitioners when he defends a certain medical treatment of appendicitis which has been so successful in his hands that it deserves the respectful attention of the whole profession—physicians and surgeons alike. The testimony on appendicitis questions is about all in, and it is simply for the settling of borderland questions that I desire to speak from the experience of a surgeon. Those of us who are physicians and those of us who are surgeons have no other object in practice than to do the very best thing for the patient who places his life in our hands—and we all comprehend the responsibility that is involved. Dr. MacArtney asks six questions, which I wish to answer *seriatim*:

(1) "What is the best treatment for outlying cases?" By outlying cases I understand him to mean the cases of appendicitis among the poor, among those who are too ill to travel, and among those who are not tractable. In such cases there has been no better treatment described than the opium treatment as shown in Dr. MacArtney's statistics.

(2) "What proportion would recover if treated medically?" This question cannot be answered by physicians, because an infected appendix containing a concretion or a stricture dam may recover from so many attacks, and in the hands of so many physicians, that years may elapse before the case can be properly quoted in statistics. The question cannot be answered by surgeons, because the cases that get to the surgeon

are not apt to include the very mild ones. It can be answered pretty well by the pathologists, however, and in the second edition of my book an analysis is made of the pathological findings in one hundred consecutive appendicitis cases in which the specimens were examined, showing that the medical death rate in that particular series of cases would have been about twenty-eight per cent. from entrapped concretions, stricture dams, strangulating adhesion bands, tuberculosis, and other causes not amenable to medical treatment. The surgical death rate in that particular group of cases was two per cent. In a series of one hundred consecutive cases of half the severity of this series, the medical death rate could be placed at fourteen per cent. and the surgical death rate at one per cent.

(3) "What proportion would relapse?" Relapse would be looked for in several classes of cases, as, for instance, those with entrapped concretions, obstructed solitary arteries, stricture dams, tuberculous foci, and thick-walled abscesses; and these include in fact about all of the appendicitis cases that are now going about the country since their recovery without operation.

(4) "What proportion of these cases if operated upon under existing conditions, would recover?" By existing conditions Dr. MacArtney means inability to receive skilled surgical attendance. I should say that the death rate at the hands of "occasional operators" would probably be as large as the death rate under medical treatment; perhaps larger. If a surgeon possessing by nature nice surgical instincts, and having manual dexterity, gives himself the benefit of a thorough special education before taking up abdominal work, he will probably save eighty out of his first one hundred laparotomy cases; death rate, twenty per cent. In his second hundred laparotomies he may get down to ten per cent. death rate, in his third hundred to five per cent., and in his fourth hundred to one or two per cent. The little bits of things which go to make up this difference in his percentages will be too small to receive attention by the "occasional operator." They are like the trifling margins of profit which roll up fortunes for large business houses and leave small houses in the lurch. When patients can have the services of the occasional operator only, surgery should be saved for a last resort instead of being tried as a pretty and safe method of treatment.

(5) "What proportion would relapse after surgical treatment?" Relapse would be looked for in cases in which the operator feared to remove the appendix when he evacuated an appendix abscess, and in cases in which a stump of appendix was left at the time of operation.

(6) "How shall we select the operative from the non-operative cases?" By looking at the appendix. There will never be any other way.

Time was when appendix questions were speculative and based on clinical experience. Now that we have exact knowledge of the pathology of appendicitis, the questions have become moral ones only, and each physician who has made a study of this known pathology is guided by his conscience in the disposition of his cases.

ROBERT T. MORRIS, M.D.

49 WEST THIRTY-NINTH STREET.

Cutaneous Classification.—John Hunter divided skin diseases into three classes: those which sulphur would cure, those which mercury would cure, and those which the devil could not cure.

Thirty Days' Credit.—The doctors of Stanford, Ky., have issued a circular giving notice that hereafter their bills must be paid every thirty days in cash or negotiable notes.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 19, 1896:

	Cases.	Deaths.
Tuberculosis.....	161	115
Typhoid fever.....	50	10
Scarlet fever.....	31	3
Cerebro-spinal meningitis.....	3	5
Measles.....	31	1
Diphtheria.....	126	21
Small-pox.....	0	0

Duration of Life among Physicians.—Dr. Salzmänn, of Essling, Germany, has made researches on this subject among the archives of the German provinces: In the sixteenth century the mean duration of life was thirty-six years and five months; in the seventeenth century, forty-five years and eight months; in the eighteenth century, forty-nine years and eight months; and in the present century, fifty-six years and seven months. These results are encouraging, and show that the favorable increase in the duration of life is due to the progress of preventive medicine and to the diminution of typhoid and small-pox.—*Progrès Médical*.

The Antiseptic Treatment of Typhoid Fever.—It is not to abort typhoid fever, as Dr. Osler apparently believes, that the antiseptic treatment is employed by the large majority of physicians who have faith in it, but because it inhibits the activity of intestinal germs concerned in fermentation and putrefactive processes and perhaps facilitate the spread of the necrotic process induced by the specific organism. To claim that antiseptics are of no value in typhoid fever because, as Dr. Osler states, they are a failure in cholera, is just as reasonable as would be the assertion that they must be efficacious because quinine, an antiseptic, cures malarial fever. There are few measures or means at the command of the physician that fulfil all the indications, and he who adopts a fad to the exclusion of all other effort, be it in the line of antisepsis or hydrotherapy, fails in his duty toward his typhoid-fever patients.—*Pittsburg Medical Review*.

The Blood in General Paralysis.—In an article on this subject in the June number of the *American Journal of the Medical Sciences*, Dr. Capps draws the following very interesting conclusions: In general paralysis, the hæmoglobin and red corpuscles are always diminished; the specific gravity falls slightly below normal; most cases show a slight leucocytosis; there is a decrease in the lymphocytes, along with an increase in the large mononuclear cells. In convulsions and apoplectic attacks, the red corpuscles and hæmoglobin are usually increased at the time of a convulsion; both are usually diminished during an apoplectic attack of long duration; the specific gravity is variable; there is a leucocytosis; the degree of leucocytosis varies directly with the length and severity of the attack; in production of a leucocytosis the large mononuclear cells are increased relatively more than any other variety. The fact that after convulsions and apoplectic attacks in general paralysis there is not only an increase in the number of white cells, but a change in their character, as shown by the differential count and that at times abnormal cells appear, is an argument against the theory that leucocytosis is merely a change in the distribution of the white corpuscles.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

A NEW CONTRIVANCE FOR INTESTINAL END-TO-END ANASTOMOSIS.

By J. FRANK, M.D.,

SURGEON TO ST. ELIZABETH'S HOSPITAL, CHICAGO.

THE numerous devices which have been introduced in the past few years for the perfection of operations upon the intestinal tract tend to show the great activity which is displayed in the surgical world in this important subject. As in medicine, in which countless drugs are recommended for one disease, the general conclusion drawn is that almost anything will do, so in this operation each man has his own device, the use of which is followed by a series of successes as well as of failures.

To point out the faults of the different devices in use is not the object of this paper, nor do I wish to convey the idea that what I am about to describe is perfect in every respect; but I will submit the result of my labors for criticism.

An ideal intestinal-anastomosis operation should embrace the following factors:

I. Quickness of operative procedure, as patients demanding this kind of surgical work are generally

FIG. 1.—Decalcified Bone Collar. *A*, inside view; *B*, outside view; natural size.

in a state of severe shock, and every minute saved is to their benefit.

II. Accurate adaptation of the severed or injured intestinal ends, with enough juxtaposition to insure sufficient surface for adhesive purposes.

To obtain this result, enough experimental work has been carried on by various investigators to convince even the most skeptical that with the introduction of some foreign substance which will temporarily hold the parts together, the surgeon's labors are greatly decreased and the patient's chances of recovery vastly increased. This leads us to the subject of material, and without going over the entire field of what each and every one has used, I will begin with a description of my contrivance, in the construction of which I have aimed at three cardinal points:

I. Material which can be safely left in the intestinal canal.

II. Time saving.

III. Simplicity of application.

The apparatus consists of two decalcified bone collars (Fig. 1) with six needle-hole perforations at the apex or shoulder of each collar, and one piece of ordinary pure gum-rubber tubing seven-eighths of an inch in length and five-sixteenths of an inch in diameter, the kind used for drainage. It is prepared for use in the following manner: a collar is slipped

over a piece of rubber tubing of the dimension stated until the apex is brought to a level with the end of the rubber tubing, when an ordinary medium-sized curved needle, threaded with No. 8 braided silk, is carried through each opening and tied; this, as can readily be seen, fastens the collar to the tube (Figs. 2 and 3); the other collar is next fitted snugly to the one already fastened, and is then in a like manner sewed to the other end of the tube. The apparatus is

FIG. 2.—Bone Collar Sewed to Rubber Tubing.

FIG. 3.—Inside View of Collar with Rubber Tubing Sewed on.

FIG. 4.—Decalcified Bone Collars Sewed to Rubber Tubing Ready for Use.

now ready for insertion (Fig. 4). The rubber tubing to which the collars have been sewed, being hollow, serves subsequently for the passage of the intestinal contents after being placed *in situ*.

It will be observed that the bases of the collars, which are formed into a broadened rim, are being held firmly in apposition throughout their entire circumference. Now the intestinal ends are brought over each collar and crowded between the line of junction of the two; of necessity the latter are forced apart, and the rubber tube is put upon the stretch, affording an adequate amount of pressure to cause a necrosis of the interposed intestines. The collars dissolving in due course of time, but a small piece of rubber tubing is left in the intestinal canal to pass off with the feces.

The following description of how the collars are prepared was kindly furnished by Messrs. Schorse & Co., of Milwaukee, Wis.

The collars are carved out of sound, very compact bone, which is obtained from the lower hind feet of a four-year-old ox. The collars are now subjected to the decalcifying fluid, which consists of a one-per-cent. solution of absolute hydrochloric acid. From this fluid the collars are removed in six hours and placed under a stream of cold water for half an hour to remove the salts which have formed. They are then placed in a fresh decalcifying fluid of the same strength and the process is repeated until they are completely deprived of their calcareous constituents, and they are washed with cold distilled water, so that all

FIG. 5.—Longitudinal Section. *A, A*, collar; *B*, rubber tubing, 10 mm. in diameter; *C*, cavity in collar; *7 M.M.*, inside diameter of rubber tubing; *20 M.M.*, length and width of collar.

traces of acids and phosphates are removed and the collars have acquired an almost transparent appearance. Now they are practically dehydrated by treatment with pure cologne spirits, and finally immersed in absolute alcohol, which renders them sufficiently tenacious for their purpose.

Having described the apparatus, its mode of prepa-

ration and construction, the experimental work upon dogs is next to be explained.

A few general remarks relative to the management of work upon lower animals may not be out of place.

As nearly as was possible, the same aseptic and antiseptic precautions were observed with regard to the hands, instruments, field of operation, and dressings as modern surgery teaches us to observe in a laparotomy upon the human subject. The dogs that were fed upon fluids prior to the operation gave less trouble at the time and thereafter than dogs otherwise fed. A dose of castor oil given the evening before the operation always cleanses the intestinal tract, and the dogs seem to do better after this.

The General Technique.—A median incision from three to four inches in length is made either above or below the umbilicus; the small intestine is drawn out through the wound, and the part to be excised is gently freed of its contents by drawing it between the thumb and index finger, when an intestinal clamp is placed at each end of the portion to be cut away, care being taken not to cut too closely to the

FIG. 6.—Murphy's Running Thread.

clamp, for if this is done there will not be enough gut to bring over the collars, which will necessitate the removal of the clamp farther back. The main mesenteric branch supplying the excised portion is first ligated with a No. 8 silk suture. From two to five inches of the gut may be resected, according to the fancy of the operator.

Upon severing the intestine, it will be observed that there is an eversion of the edge of the bowel and also a contraction, producing a circular constriction at the end of the intestine; this can be easily overcome by inserting a finger into the lumen of the gut and retaining it there for a minute or two, thus producing a temporary paralysis and allowing a much easier manipulation of the parts; this stretching of the gut must be gently performed, otherwise the peritoneal covering will split longitudinally. A straight or curved needle threaded with No. 8 silk is used for inserting Dr. Murphy's puckering string (Fig. 6), a description of which can be found in the *New York Medical Record*, vol. xlii., p. 673, 1892, to fasten the intestine about the rubber tube after the former has been slipped over the collars. The puckering string is similarly inserted into the other intestinal end, and the bone collars, having been previously prepared as described, are taken out of the absolute alcohol in which they were placed immediately after being sewed to the rubber tubing. The operator slips an intestinal end over one of the collars to the line of junction, at the same time gently spreading the collars apart to facilitate the easy access of the gut. An assistant takes charge of the ends of the puckering string, and when the gut has been brought over the collar he makes one knot and draws down until his puckering ligature strikes the rubber tubing, which he will perceive by the resistance offered; the tube will not generally permit a too tight

drawing of the puckering ligature on account of its resiliency, but, to make absolutely sure that the tube is patulous, the end of a forceps or sterilized nail may be passed through the lumen; if this is found pervious the assistant finishes the tying of the puckering string. The other intestinal end is then slipped over the remaining collar and also tied. Of course at this stage nothing can be inserted by which to determine that the tube is not shut off, but, after having tied one side, the assistant will positively know when he strikes the tube. The ligature is cut off short and the clamps are immediately removed, when the operated portion of the bowel will be slowly distended with gas. An interrupted or continuous Lembert suture should be taken around the border with an intestinal needle, threaded with No. 2 silk, which makes the work more secure.

The rent in the mesentery may or may not be sewed. In those cases that were sewed catgut was used; any bleeding vessels should be tied with catgut. The intestine is returned into the abdominal cavity as nearly as possible in a straight line, the site covered with omentum, and the abdominal wound closed in the ordinary manner. The wound is powdered with iodoform and a collodion dressing applied; gauze and cotton are placed over this, and then the bandage.

Experiments.—**EXPERIMENT II.**—May 16, 1896: black Newfoundland bitch; weight, fifty pounds. End-to-end anastomosis with wooden model (the bone collars not being ready). Time of operation twenty-eight minutes. No Lembert sutures were taken, as they were not necessary. The dog was playful after operation.

May 20th, four days after operation, the bowels moved primarily.

May 22d, six days after date of operation, the wooden model passed with a bowel movement. The tube was patulous.

May 23d, seven days after operation, the abdominal wound was entirely united and the dog was well and very playful, and continued in this manner up to May 30th, when it was observed that the animal acted rather sickly. She died June 1st, fifteen days after the operation.

Post-mortem: Perfect union at site of operation. Below this protruded a sharp spiculum of bone; immediately below this was found a mass of hay and hair matted together. The protrusion of bone was caused by a spur in the gut below the site of operation. The cause of death was purulent peritonitis.

EXPERIMENT IV.—May 30, 1896; male Newfoundland; weight, seventy pounds. End-to-end anastomosis with decalcified bone collars. After the collars were *in situ*, a continuous Lembert suture was taken, although there was no gaping, but it was deemed advisable to do this, because the bone collars were not quite hard enough.

June 5th, six days after date of operation, the bowels moved and in the fecal mass the rubber tube was found (Fig. 7), which had held the bone collars together. About the tube were the puckering strings and at each end of it were the sutures which were used to fasten the collars to the tube; no trace of the collars could be discovered. The dog is well and playful to this date, September 14, 1896. Time of operation twenty-five minutes.

EXPERIMENT V.—June 7, 1896; black Newfoundland; weight, forty-five pounds; end-to-end anastomosis. After collars were placed *in situ* a continuous Lembert suture was taken, as the bone collars were still not sufficiently hardened.

June 12th, five days after operation, the bowels

FIG. 7.—Rubber Tubing showing Puckering Thread in Centre and Sutures at Ends after Bone Collars had Dissolved. Experiment No. 4.

moved for the third time, and in the faecal mass the rubber tube and puckering sutures were found.

June 13th, five live pups were born to patient and a dead one.

June 14th, three more pups arrived, making nine in all. The stitches were removed too early and twelve

FIG. 8.—Perfect Union Fifteen Days after Operation. Lembert Suture Presenting at Inner Surface of Intestine. Experiment No. 6.

inches of intestine protruded through an opening in the lower angle of the abdominal incision. The protruded gut was inflamed and adherent to the gauze dressing. It was gently freed from the gauze by means of lukewarm sterilized water and replaced into the abdominal cavity, and the lower end of the incision again united.

June 17th, the dog had made a complete recovery, and is alive and well to this date, September 1st. She has a large hernia at the lower site of incision. Time of operation, twenty-four minutes.

EXPERIMENT VI.—June 9, 1896; male; weight, fifty-five pounds. End-to-end anastomosis with decalcified bone collars.

June 15th, six days after date of operation, rubber tubing with puckering strings passed in faecal mass.

June 17th, dog was well and lively.

Post-mortem: June 24th, fifteen days after operation, to see the condition of affairs at site of operation. Union was perfect. There was adherent to the peritoneum at the site of incision an omental mass, free from

FIG. 9.—Perfect Union Twenty-three Hours after Operation. Decalcified Bone Collar Still in Place. Experiment No. 8.

intestine but including a portion of the pancreas. The site of the operation was eight inches from the stomach. One end of the Lembert suture presented internally (Fig. 8). There was a slight narrowing of the lumen of the bowel at the site of operation, due to the inflammatory condition of the surrounding omen-

tal mass. The mucous membrane was smooth, especially opposite the mesentery.

EXPERIMENT VIII.—June 17, 1896; Newfoundland, female; weight, forty-eight pounds. Dog was killed twenty-three hours after the operation to obtain a specimen of site at an early period. The abdominal incision was united. The site of operation was covered by plastic omental adhesions. No pus, no peritonitis, and no adhesions to abdominal parietes. The site of operation and the adjoining five inches of gut on each side were excised, a fountain syringe was attached to one end, and the stream passed through very readily; the distal end was then clamped and the gut filled to its entire capacity without leakage occurring. The collars were in the same position as at the time of operation and were fairly hard. The mucous membrane in the vicinity of the collars was reddened to a slight extent (Figs. 9 and 10).

EXPERIMENT IX.—June 20, 1896; female; weight, forty-one pounds. Time of operation, twenty minutes. Dog playful after operation.

June 21st, bowels moved.

June 23d, three days after operation, one undissolved collar and the rubber tube, as well as a part of the remaining collar, passed with the bowel movement.

June 24th, four days after operation, dog was killed to

FIG. 10.—Twenty-three Hours after Operation. Showing Line of Union Externally. Experiment No. 8.

obtain specimen (Fig. 11). The abdominal wound was entirely healed; no suppuration nor peritonitis; intestines empty; slight redness about the site of operation, to which was adherent, slightly, part of the omentum and intestine. The intestine at the time of operation was returned to the abdominal cavity in a straight line, but at the post-mortem there was found a bend at the operated portion. Water passed through the gut freely, and was also retained after one end of the intestine had been closed. When the spur (bend) was straightened, part of the Lembert suture presented itself at the mesentery; there was a thickened ring about the circumference of the united intestines; the mucosa was not inflamed. An intussusception, three and one-half inches in length, was found fifteen inches below the seat of operation, through which water passed readily.

EXPERIMENT X.—June 26, 1896; female; weight, forty-five pounds. Time, twenty-one minutes. Chromicized catgut, corresponding in size to a No. 8 silk, was used for the continuous Lembert.

June 28th, fifty-six hours after operation, the dog died. The post-mortem was held immediately after, with the following facts noted: General peritonitis. One collar was partly dissolved, the other only softened. When water was passed through the operated portion leakage occurred at several points through the needle perforations of the Lembert suture. The mucosa was

inflamed and thickened two inches above and below the seat of operation. This dog, after the operation, was placed on carpet which had been used by a dog that died of peritonitis. This may explain the infection.

EXPERIMENT XI.—June 26, 1896; female; weight, fifty-five pounds; time, fourteen minutes. No. 2 silk used for Lembert sutures.

June 29th and 30th, bowels moved.

July 1st, five days after operation, bowels moved again, and in the hardened fecal mass the tube and one partly dissolved collar was found. The dog was playful and seemed to be well. Immediately after the tube had passed the dog was killed.

Result of post-mortem: No peritonitis. Adhesions to the surrounding intestines and omentum had formed. The resected portion of gut adhered to itself so as to form a loop. Water passed through it freely; under great pressure of stream the adhesions gave way, and there occurred a small leak at the line of union. The Lembert suture presented internally (Fig. 12).

EXPERIMENT XIII.—June 30, 1896; female; weight, fifty pounds. In this experiment no Lembert suture was taken. Time, three minutes.

Post-mortem: General peritonitis, resulting from

FIG. 11.—Four Days after Operation. Showing Elevation at Seat of Operation Internally. Experiment No. 9.

non-union. The edges of gut had slipped out from between the collars, the latter not having sufficiently hardened.

EXPERIMENT XVI.—July 22, 1896; No. 2 continuous Lembert suture taken; time, twenty-two minutes.

July 26th, four days after operation, the dog died. Post-mortem: Perfect union. Cause of death, intussusceptions, of which two were found. One was twenty-four inches in length, being twenty inches from the anus; at the proximal end of this intussusception one undissolved collar was found. The other intussusception was found nearer to the rectum. Under high pressure water passed through both intussusceptions and reduced them. In one the intussusciens was gangrenous.

EXPERIMENT XVIII.—August 1, 1896; female; weight, thirty-five pounds; time, nine minutes for inserting the collars and twenty-five minutes for entire operation. The tube was passed on the sixth day. Interrupted Lembert sutures were taken with No. 2 silk.

September 10th, killed to obtain specimen. Dog was in fine condition. No adhesions to line of incision. Union perfect. Omentum slightly adherent to intestine opposite mesentery. Seat of operation, thirteen inches from rectum.

EXPERIMENT XIX.—August 1, 1896; female; weight,

forty-five pounds. Interrupted No. 2 Lembert sutures taken. Time, seven minutes for insertion of collars and eighteen minutes for entire operation. Dog acted

FIG. 12.—Perfect Union Five Days after Operation. Lembert Suture Presenting at Inner Surface of Intestine. Experiment No. 11.

well, but was killed after forty-eight hours to obtain a specimen.

Post-mortem: Beginning peritonitis; collars were undissolved and brittle, but softer than at the time of insertion. Site of operation ununited. The edges of gut were cut off by the collars throughout the entire circumference.

EXPERIMENT XX.—August 8, 1896, male; weight, seventy pounds. Operated by my assistant, Dr. Sylvan Kunz. Four interrupted Lembert sutures taken. Tube was passed the sixth day.

September 10th, forty-one days after operation, the dog was killed to obtain a specimen. There were no adhesions to the abdominal incision. The line of union in the gut was perfect, and a small strand of omentum was adherent to it. The resected portion of gut and the two adjacent inches on each side were excised. Upon passing the finger through the bowel a slight constriction was felt at a point corresponding to the line of

FIG. 13.—Thirty-three Days after Operation. *a*, Line of Union; *b*, Omentum. Experiment No. 20.

union. Upon laying the gut open, a perfectly smoothed mucosa presented (Fig. 13), the line of union being barely perceptible.

Summary of Experiments.—Of the thirteen dogs operated upon, nine made complete recoveries. One dog (Experiment VIII.) was killed after twenty-three hours to obtain an early specimen; from the appearances at the post-mortem the dog would in all probability have lived. In Experiment X. the dog died of general peritonitis, probably infected from carpet upon which he was placed immediately after the operation. In Experiment XIII. the intestines slipped from the collars, owing to their extreme softness, resulting after three days in the death of the animal from general peritonitis. In Experiment XVI. the cause of death was gangrene of the intussusciptions. In the next series of experiments I hope to obtain better results, as I have greatly profited from those just completed.

In conclusion, I beg to state that although I have not yet been able to try the collars on a human subject, I am convinced beyond a doubt that they will prove successful. The small piece of rubber tubing which is left to pass off will certainly not produce any obstruction, nor is it at all apt to ulcerate through the bowel. In regard to the resulting constriction of the lumen of the bowel, I am satisfied that it is no greater than that following the use of any other contrivance. Although the experiments are not very great in number, I am anxious to have them reported, so as to give any one who may see fit an opportunity to try the decalcified bone collars. It is my intention to add to this article from time to time. The series of experiments upon cholecystenterostomy and gastro-enterostomy will be published separately. I am greatly indebted to my student, Mr. Leon Feingold, of the College of Physicians and Surgeons of this city, for his faithful attention and assistance throughout my experimental work.

The longitudinal section (Fig. 5) was kindly furnished by Prof. Herman Haustein, of this city.

THE TREATMENT OF PNEUMONIA.¹

BY BASIL M. TAYLOR, M.D.,

GREENSBURG, KY.

BACTERIOLOGISTS in the last ten or twelve years have shown that acute lobar pneumonia is an acute specific disease due to a specific micro-organism, the diplococcus pneumoniae. They have demonstrated its presence in the exudation in the lungs of patients who have died with acute pneumonia and in the characteristic brick-dust sputum of patients sick with the disease. Clinical experience and research have failed to prove that pneumonia, though caused by a specific organism, is a contagious disease. There are, however, reports of epidemics in countries of dense population and especially in barracks where a good many are crowded together. There is no evidence that one soldier took it from another, but that they were all subject to the same influence. The germ is widely spread, as pneumonia is known throughout the world.

Every disease produced by a specific micro-organism must have that special micro-organism present and that special micro-organism must reproduce the disease when introduced into the system of persons or of animals who are not immune. The sheep, dog, rabbit, and the field mouse are not immune, and when the bacillus is introduced into the lung by injection they die in a few days from a typical lobar pneumonia. Experiments have shown that when the bacillus was injected into the blood of the peritoneal cavity they did not develop pneumonia, but either recovered or died speedily from septicaemia; but when large

injections of the cultures were made directly into the lungs they died from acute lobar pneumonia.

Many, however, deny that this diplococcus pneumoniae is the cause of pneumonia because this germ has been found in the saliva of healthy persons. Many a tubercle bacillus has been swallowed, inhaled, and carried around in the secretions of healthy persons who did not contract tuberculosis, but no one in his right mind will dispute the fact that tuberculosis is produced by nothing but the tubercle bacillus, and that people die every day with tuberculosis. It is out of place here to discuss at length why all people who possess somewhere about them a specific germ do not develop the disease produced by that germ. I merely give this introduction to this paper to show that I think that pneumonia is produced by a specific germ and that that germ is necessary for the production of pneumonia.

Taking it for granted, then, that acute lobar pneumonia is produced by the bacillus crouposae pneumoniae, it is a specific and self-limiting disease. It runs its course like all other specific diseases not having a specific remedy, uninfluenced so far as curing or aborting it is concerned, by any means at our hands. There are cases, however, that run a very short course and seem to be aborted in their incipency; but such cases I think are either not pneumonia, or the micro-organism is not developed properly, or is overcome by some antitoxin in the person affected, or the condition of the lung is not such that the organ offers a favorable place for its development at that time. I do not hold to the opinion that any specific, self-limiting disease can be aborted by internal medication.

Having, therefore, a specific disease produced by a specific organism that causes inflammation of the lung and by its special action produces a toxin oftentimes so fatal to both extremes of life—and the adult also is by no means immune—the only scientific and “the way” to treat such a disease is by an antitoxin that will at once destroy the vitality and development of the bacillus and counteract the effects of the toxin upon the patient. We are now just in the dawn of this scientific principle—orrhotherapy. We will all welcome the day when each specific toxin will at once be met with a suitable antitoxin. Not until then will the physician be armed with the sword of a “sure cure.” Remedies, then, at our hands are only uncertain aids to nature.

Of the ways of treatment as suggested by different writers and the remedies in the materia medica there are many. I suppose every physician has his own favorite prescription that he gives to every patient upon his first visit, whether it be in the first or last stage.

What is indicated in one stage is, perhaps, contra-indicated in another. The strong and robust demand a different treatment throughout from that required by the weak and nervous. Pneumonia, therefore, is a disease for which there is no routine treatment applicable to every case, and the physician who fails to realize this falls far short of his duty to his patient and to himself, and such a physician fails oftentimes to do good and when he does no good he will do harm. We must individualize and not generalize. The physician who prescribes solely from experience has his face turned from professional advancement, and will sooner or later be a source of danger to his patients.

In the treatment of pneumonia there are many things to consider. We must consider the age of the patient, the stage of the disease when first seen, the condition of the patient, whether robust and plethoric or weak and anæmic, and the surroundings of the patient. We must look after the pain, the shock, the temperature, the stimulation or heart depressants, sleep, and the nourishment.

¹ Read before the Green River Medical Society, at Campbells-ville, Ky., July 3, 1896.

In pneumonia, near the surface of the lung, there is always pleurisy, and this is the cause of the pain. Severe pain is capable of killing of itself and always to a certain degree causes shock. Shock, of course, gives the patient a feebler power of resistance. We have many remedies to control pain—opium or its alkaloids in some form, heat or cold applied locally, chloral hydrate, counter-irritants, and the coal-tar preparations.

Morphine stands at the head of the list. It controls the pain, gives the patient rest, and produces quiet and refreshing sleep, prevents shock, stimulates the breathing and heart, prevents vasomotor disturbances in the circulation and thus in a degree keeps some blood from the already overloaded heart and lungs. Quieting the nervous patients, it prevents a higher degree of fever, from which they suffer more than the healthy and robust in a disease of equal severity. Some may object to it on account of its tendency to check the secretions and thus overload the system with waste products. In doses sufficient to quiet pain and give the patient rest, I have seen no such bad effects from it, and its good effects are so many and so noticeable, and so far overbalance its evil effects, that such objections should without hesitation be overlooked. By giving rest and sleep and preventing shock, it many times tides the patient safely over what might have been a fatal period had he been allowed to suffer. Chloral hydrate is of doubtful utility and should be used with caution. When there is no pain and not much depression of the arterial tension, and the patient is restless and nervous, chloral might be given in doses sufficient to quiet. I have had very little experience with hydrotherapy, and, in view of the position that I took in the beginning of my paper, I consider it of doubtful utility, available only to relieve pain and as an antipyretic. Water has no virtue sufficient to cut short or modify the course of the disease. Routine hydrotherapy is capable of doing harm. The treatment of inflammation as laid down in our textbooks of surgery is to apply cold or heat in some way. As pneumonia is due to micro-organism and is a self-limiting disease, water cannot promise anything. A pleurisy might be benefited by the ice bag or coil, but in pleuro-pneumonia it should be used with caution and its effects carefully watched. In the nervous patients who are suffering from a severe attack, and in whom there is decided shock evidenced by cold extremities and rapid breathing and feeble pulse, cold applications on any part of the body will only make matters worse by increasing the congestion of internal organs and exposing the patient to greater shock. Such cases need a dose of morphine and strychnine and hot applications to the body and extremities, which help to relieve the pressure on internal organs already overloaded with blood. Cold applications are to be limited, I think, to those of robust constitution and with a pneumonia near the surface. Cold applications must be used with caution and must never chill the patient. Their field of usefulness must necessarily be limited. They can be used to no advantage whatever in any except the first stage and we rarely ever see a patient in the first stage in time to apply them to an advantage. When the lobe is about filled with exudation, cold water has no place. Selecting, then, a suitable case in the first stage of the disease, cold applications for a day or two only may be of some benefit to the patient, but after the first stage tepid sponging to allay fever and restlessness and to promote the action of the skin is, I think, the only field for hydrotherapy in pneumonia.

The function of the bowels and kidneys must be watched with a never-tiring care. These are the sewer pipes of the system, and if they are hindered in their action our patient may die and we charge it to

the pneumonia. Each case is a law to itself. Routine practice does not guide us here. If there is a diarrhœa, its cause must be looked into and removed, and the diarrhœa checked. It may be from some pill that the patient has taken to arouse his, as he thought, torpid liver; it may be from an attack of indigestion preceding the attack of pneumonia; it may be a case of chronic diarrhœa; it may be the beginning of an attack of typhoid fever; it may be from an ulcer or two in the colon; it may be a vicarious diarrhœa relieving the system of waste products caused by the checking of the function of the skin or kidneys. We must look into the cause and then treat the case accordingly. It is dangerous to check the diarrhœa and leave the function of the skin or kidneys completely checked or embarrassed. Remove the cause and then check the diarrhœa.

On the other hand, if there is constipation, relieve it by giving some mild cathartic. The bowels ought to move once or twice in the twenty-four hours. It is a common practice among physicians to give a dose of calomel at the first visit, whether the case be one of fractured femur or of typhoid fever. I am glad to say that I am not a mercurial fanatic. If the patient has a torpid liver in the first stage, give him a mild calomel purge; but if his liver is acting correctly, keep your calomel in your saddlebags or take it yourself. If you want to move his bowels, give him a good saline cathartic. This will relieve to some extent the congested lung and will not weaken the patient nor make him sick at his stomach as will a dose of calomel. If the patient demands it, keep his bowels loose with Rochelle or Epsom salts.

We must inquire carefully into the action of the kidneys and learn if possible if Bright's disease exists. If we overlook this important duty, the kidneys might be suddenly overwhelmed by the poison in the system and our patient die before we realized what is the matter. Forewarned is forearmed. If you would discharge your whole duty toward your patient and anxious friends, be ever upon the alert, and you will never have the remorse of conscience that tells you that one death is charged to your carelessness and ignorance. The sum total, then, is to keep the bowels, skin, and kidneys constantly performing their whole duty. The temperature of the patient should demand our careful attention and at no time be allowed to remain very high. A temperature of 101° F. does not demand much in the way of antipyretics. Nothing is more dangerous and uncomfortable to a patient than a prolonged high temperature. Many medicines are recommended as antipyretics—quinine in large doses, the coal-tar preparations (of which there are several), aconite, and sponging with cold or tepid water. I have no use for quinine as an antipyretic. Of course if there is malaria, quinine should be given in doses large enough to destroy the plasmodium. In every case in which it is practicable a blood examination ought to be made to determine its presence or absence. In the first stage quinine in small doses often repeated may be of some service. Of the coal-tar preparations antifebrin is my favorite. It acts better and is not so depressing as the others. I give it in from three to five grain doses every three hours, or just as often as is necessary for the reduction of the temperature. Sponging with tepid water, often repeated, is of value.

The cough demands careful attention, for, although only a symptom, it may be very distressing. The sputum is always tenacious and hard to be expelled. The tenacious sputum should not be allowed to collect in the air passages any more than can be helped by remedies at our hands. Expectorants should be given freely until the cough is no trouble to the patient. The mixture that I prefer is composed of ipecac in

small doses, carbonate of ammonium and potassium in from five- to ten-grain doses in syrup of wild cherry, and tolu or brandy every two or three hours, according to the demands of the case. The ipecac promotes expectoration and the carbonate of potassium keeps the tenacious sputum almost liquefied. It thus loses its tenacious character and the patient keeps his air passages pretty free from it with very little exertion. The carbonate of ammonia acts as a heart and respiratory stimulant and stimulant expectorant.

Delafield, in Pepper's "Practice of Medicine," vol. ii., recommends for the treatment of the exudation digitalin and aconitine and, if the pulse demands it, whiskey. This treatment is applicable to only a certain class of patients. I have had no experience with this treatment. Venesection is recommended in those who are plethoric and with a full bounding pulse. When performed carefully and in a selected case, it is useful in the first stage. I have never employed this plan of treatment.

The employment of stimulants requires good, sound judgment in regard to the time to use them and the amount to use. Many patients do not require stimulants in the first stage. If the temperature is kept low and the patient free from pain, he will not need much stimulation until later in the disease. We must judge by the failing pulse. I never give stimulants until I find them indicated. I condemn the indiscriminate use of them—that is, to give stimulants because your patient is sick and you think he must have medicine in some form. When the pulse is rapid and weak I give brandy or whiskey, from one to four tablespoonfuls every three hours, according to the demands of the case. Its effects should be carefully watched, and if the patient show signs of irritation from it it should be withdrawn or lessened in quantity. Just enough should be given to meet the demands of the case and no more nor less. It is useless to give an excess, because it throws more work on the excretory organs. I will call special attention to strychnine as a heart and nerve stimulant. Very often it will be all the stimulant that is required throughout the case. It stimulates the heart, gives the patient more strength, and prepares his system to meet the shock of the disease. I give it as a rule throughout the attack. It acts better hypodermically. It ought to be given in one-thirtieth to one-sixtieth grain doses every three hours during the day.

Sleep is as important as medicine. If my patient can do so, I generally allow him to sleep most of the night undisturbed. Patients in any disease who are aroused every hour during the night to take a dose of medicine will gain very little rest, and if we are not careful they will die from the loss of sleep if not from the disease. I combine my medicines as much as possible. I put heart tonics and diuretics in the same dose and let them be given with the antipyretics, and thus avoid so many different hours. If the case is not desperate, I allow the patient to have a little nourishment and a few doses of medicine through the night, but these only when he awakes himself. A good night's rest will do as much good in many cases as all the drugs in a store. If the patient is kept easy and the temperature low, he will as a rule sleep most of the night. Of course, when the case is desperate and the heart is rapidly failing, medicine must be given regardless of sleep.

The patient should at all stages of the disease be well nourished. His diet should be liquid and easily digested. Milk is the best food when it can be well borne. Beef tea, soups, and koumys may be given with benefit. The diet should be composed of several different articles. If one article alone is given, the patient gets tired of it and his stomach is irritated by its presence. Egg-nog is useful both as a stimulant

and a food, and it is usually relished by all patients. When the stomach is irritable and nothing can be retained, the white of an egg shaken up in a glass of lemonade will nourish the patient and stop the vomiting. Thus no valuable ground will be lost.

I will not speak of the complications and sequelæ here. They must be treated according to the requirements of the case, whether it be medical or surgical. I have given you my method of treatment, which has at my hands proven very satisfactory. All we can do now is to make the best of what we have at our hands and to wait with eagerness the coming of a specific antitoxin with which to meet so fatal a toxin.

July 3, 1896.

SYPHILITIC DISEASE OF THE SPINE.

By L. HARRISON METTLER, A.M., M.D.,

CHICAGO, ILL.

OUR knowledge of spinal syphilis is limited; it is less than our knowledge of cerebral syphilis. Nevertheless, a sharp distinction should always be made, when possible, between syphilitic disease and other affections of the cord that may resemble syphilis. The former is, as a rule, amenable to treatment, and in its early stages affords a hopeful prognosis; the latter less often so. It should always be remembered that while spinal syphilis has its own pathology and symptomatology, there are many affections of the spine—as, for instance, the various sclerosis and degenerations—which are not strictly syphilitic diseases, though often following syphilis. This is notably the case with posterior spinal sclerosis. In the former, the lesions are purely syphilitic, being produced and maintained by the direct action of the specific toxic element in the blood. In these cases antisiphilitic treatment, that controls the syphilitic infection, exerts a direct and curative force upon the syphilitic lesions. In the latter, however, the lesions are more in the nature of sequelæ, the remains after the storm has passed. They are mostly of the degenerative sort, and, therefore, are not permanently benefited, though occasionally slightly so, by antisiphilitic treatment.

The diagnosis of spinal syphilis can be made at the present stage of our knowledge only from the history of the case and by the exclusion of all other diseases of the cord. Certain gross syphilitic lesions—such as meningeal inflammations (about which, however, there is much controversy) and tumors of the spinal canal and cord proper—are easily recognized and their nature readily comprehended when associated with a history of specific disease. There are those who deny that meningitis and myelitis are ever directly due to syphilitic infection. They also hold that the continuous or tract sclerosis and many of the chronic inflammations are not distinctly syphilitic. There is hardly a spinal-cord degeneration that has not occurred in a syphilitic patient some time or other, but these same degenerations have been found in non-syphilitics as well. Hence it is still an open question just what is syphilis of the spine and what is not. The relationship between syphilis and the spinal-cord degenerations is not yet clearly wrought out, and I will, therefore, not consider these degenerations at present under the head of spinal syphilis.

There are certain manifestations of spinal syphilis that so simulate other affections of the cord, and are in themselves so indefinite and irregular, as to render a diagnosis a matter of extreme nicety. In such cases a course of antisiphilitic treatment has sometimes to be resorted to before any diagnosis can be made. The more we can avoid, however, such indirect empirical methods of making diagnoses and the more we can depend upon the direct manifestations of the disease, the

better it will be for the patient and the more creditable to the science of medicine.

Syphilitic disease of the spine begins within a short time after infection; it progresses slowly, and exhibits a remarkable tendency to improvement as a result of vigorous antisyphilitic treatment. Erb, of Heidelberg, states that its frequency in proportion to posterior spinal sclerosis is as one to ten. Muchin, of Charkow, believes, on the other hand, that it is far more frequent than Erb supposes.

Huebner, writing for Ziemssen's "Cyclopædia of the Practice of Medicine," enumerates four general forms of spinal syphilis:

First, neoplasms of syphilitic origin, including single tumors and small multiple and disseminated formations on the spinal membranes.

Second, syphilitic callus: there being found post mortem a circumscribed induration of the cellular tissue about the cord, generally with adhesions of the dura mater.

Third, simple softening of the cord. This Steenberg describes, though Huebner doubts whether it should be considered a distinct syphilitic lesion. He also doubts the existence of a pure syphilitic myelitis.

Fourth, cases in which symptoms of acute ascending paralysis (Landry's paralysis) occur without discoverable post-mortem findings.

After giving a report of a case which manifested symptoms to classify it with Huebner's fourth series, Wood ("Nervous Syphilis") states that he doubts whether these cases ought to be regarded as syphilitic at all. Certainly his own case, of which it was difficult to obtain a complete autopsy, resembled one of peripheral neuritis as much as anything else. The cases of Huebner and Kussmaul were not examined for lesions of the peripheral nerves, so that the fourth class, as a form of spinal syphilis, has scarcely been established.

In the production of the second and third classes of Huebner, syphilitic infiltration and gummatous formations play an important rôle: so that the softening of the cord and the development of callus should be regarded in the light of secondary effects rather than as direct syphilitic lesions of the cord.

This leaves only the first class to be considered. Syphilitic neoplasms are generally connected with the spinal membranes. They may grow inward upon the cord and produce destruction of the medullary elements and even chronic inflammation and softening; or they may extend outward and cause agglutination of all the spinal membranes, pressure of the nerve roots, and even disease of the osseous vertebræ. There are probably, therefore, two forms of spinal syphilis or gummatous disease of the spine—that in which the membranes are chiefly the site of the disease (Wood), and that in which there is an infiltration of the cord from its own vessels (Rumpf).

When examining a case of suspected spinal syphilis, it is necessary to remember that the lesion may be meningeal, producing symptoms similar to those of non-specific spinal meningitis; and that, on the other hand, it may consist of an infiltration of the medullary substance itself, giving rise to symptoms indicative of destruction of the sensory motor tracts. When the gummatous disease is meningeal, the earliest symptoms will be those of pain or paræsthesia and spasm or paresis, due to compression and irritation of the anterior and posterior nerve roots. Of course, the sensory symptoms will be referred by the patient to the peripheral terminations of the nerves whose roots are undergoing irritation. The principal difference between gummatous disease of the meninges and simple non-specific subacute or chronic meningitis, is that the symptoms of the former are apt to be more sharply defined or localized than those of the latter. The rea-

son for this is obvious, since the former lesion is more in the nature of a tumor with comparatively well-defined limits.

According to Erb, the symptoms of syphilitic disease of the spinal cord closely resemble those of myelitis transversa dorsalis; but the two are, nevertheless, distinguishable by a number of typical signs. The walk, posture, and motion are quite characteristic, and simulate those of spastic paralysis. The tendon reflexes are apt to be marked, without much muscular tension.

The pains, when present, are usually sharp and cutting, and when the lesion is located in the dorsal or lumbar region they assume the girdle form. Not unfrequently they resemble the lightning pains of tabes dorsalis. Rarely are they dull, aching, and continuous. Often there is no pain at all. On account of the usual meningitis accompanying the gummatous deposit, there is more or less local tenderness of the spine on pressure. Wood states that in several instances this local tenderness was attributable to involvement of the vertebral periosteum and vertebræ. All the various sensations common to local meningitis are characteristic of this form of spinal syphilis, such as numbness, formication of the extremities, "pins-and-needles" sensation, and other bizarre paræsthesiæ down to the ultimate condition of complete anæsthesia. There is always distinguishable impaired sensibility, but severe pain is not generally felt, according to the observations of Erb. Atrophy is not present. There is little or no involvement of the head and cerebral nerves. Rarely are the muscles of the eye implicated. There is nothing abnormal psychically.

The motor symptoms are the same as those of localized non-specific irritative meningitis, such as rigidity of the neck and limbs, tremors, exaggeration of the reflexes, severe cramps excited by movement. Later on, complete paralysis supervenes. If the palsy increases rapidly after long-continued disturbance of sensation, it is almost pathognomonic of syphilitic disease, according to Wood. The sphincters are generally included in the final symptoms. Bedsores and other trophic troubles occur, often with elevated temperature and general septicæmia.

In a case of syphiloma of the cord and cauda equina, reported by Osler, death occurred from diffuse central myelitis. There were pains in the legs, particularly in the left, which underwent rapid wasting and presented vasomotor changes. There were pains in the arms, especially the right, without wasting. There was absence of control of the bladder and rectum for two months before death. There were bedsores and arthritis in the knees and ankles. Toward the close of life high fever with delirium came on. There was a gumma in the antero-lateral columns of the cervical cord, opposite the right fourth anterior nerve root. Gummata also involved the third, fourth, and fifth anterior sacral nerve roots, and the second and third posterior sacral roots on the left side. Many of the symptoms in this case were due to the accompanying lesions resulting from the presence of the syphilitic new formations. A differential diagnosis in such cases, though extremely difficult, is important if at all possible. The treatment of simple spinal syphilis, before the advent of the resulting inflammation and degeneration, is a relatively easy matter; but when extensive destruction of the nervous elements has already set in, the prognosis is that much more unfavorable.

In syphilitic disease of the upper cord there may be diplopia, amblyopia, and pupillary irregularity. Tinnitus aurium occurred in a case reported by Weber.

The symptoms of the second form of spinal syphilis, namely, syphilitic infiltration of the cord, are usually slower in their onset and vary according to the location of the lesion. As the latter is more or less dif-

fused, so will the symptoms be more or less indefinite. They will range all the way from hyperæsthesia to anæsthesia, from spasm to paralysis. Spastic paraplegia without much pain is highly indicative. Sometimes the symptoms closely resemble those of locomotor ataxia. True syphilis of the cord does not follow the course of the sensory and motor tracts as do the various systematic scleroses and subsequent degenerations. The symptoms are, therefore, much more mixed and indefinite.

The diagnosis of spinal syphilis is best made by the exclusion of other spinal affections and by remembering that any one of these other affections, associated with a history of syphilis and presenting more or less unusual manifestations, is very apt to be syphilitic in origin. If a case of apparent locomotor ataxia, for instance, shows an absence of the usual fulgurating pains or the presence of the patellar reflex, spinal syphilis rather than posterior spinal sclerosis should at once be thought of.

The prognosis of spinal syphilis should always be guarded, even though great improvement is obtained sometimes by appropriate medication. Occasionally absolute cures have been made. More often, however, the delicate constituents of the cord have been irreparably damaged when the case first comes under observation, and then only a prevention of further injury can be hoped for.

The treatment usually resolves itself into the administration of mercury and the iodides. The object is to neutralize at once the syphilitic poison, to sustain the vitality of the cellular structures, and to remove as quickly as possible any gummatous enlargements that may be exerting a deleterious pressure. Each case is a law unto itself, but in all cases bold, heroic treatment is usually needed to check at once all further damage of the nervous elements. Hot and cold spinal douches, suspension, massage, all have their applicability in the appropriate cases. The indications are the same as in any of the various forms of organic disease of the spine. Spinal syphilis should be managed just as any other disease of the cord and its membranes, plus the administration, heroically and for a long period of time, of the requisite antisyphilitic remedies.

4544 LAKE AVENUE.

INFANTILE SCORBUTUS.¹

BY H. M. McCLANAHAN, A.M., M.D.,

OMAHA, NEB.,

PROFESSOR OF DISEASES OF CHILDREN, OMAHA MEDICAL COLLEGE.

A VERY large number of diseases of infants have their origin in errors of diet. The paramount question during the first year of life is proper care and nutrition. A well-born baby of rich possibilities may, on an imperfect food, become stunted and anæmic and permanently deformed. The correct and complete nourishment of the infant is essential to perfect development. During this period of life growth is rapid, cell proliferation abundant and of low resisting power; hence the lack of supply of correct nutritive material soon manifests itself, not only in impaired nutrition, but in actual organic disease as well. Primarily, malnutrition may come about in two ways: by lack of some element or elements of food or by improper digestion or imperfect assimilation of ingested food. Both causes may and usually do operate conjointly. From an important group of diseases having their origin in want of perfect food supply, I select for your consideration one, namely, infantile scorbutus.

The credit of giving this disease a distinct place in

nosology belongs to W. B. Cheadle, of London, who described three cases in the London *Lancet* in 1878 as true scurvy. Previously to this, isolated cases had been noted in Germany by Moeller, Bohn, Hirschsprung, and Senator as examples of acute rickets, and one case in 1873 by Ingeler as infantile scurvy. The first case recorded in England was in 1876, by Mr. T. Smith, and called by him hemorrhagic periostitis. Similar cases were described in 1881 by Dr. Gee, under the name of periosteal cachexia. In 1883 Dr. Barlow in the *Medico-Chirurgical Transactions*, vol. lxi., gave the history of eleven cases under his care and twenty cases from other sources. He also gave very fully the morbid anatomy of infantile scorbutus. As a result the disease is called by his name by a number of writers, Osler of this country among them.

Etiology.—A search of the literature of this subject reveals the following: The disease is never seen in the infant nursed at its mother's breast and probably never in the infant fed on fresh cow's milk. In the cases reported by Cheadle, the greater number of patients were fed on farinaceous foods; some on desiccated patent foods, a number on condensed milk, and several on pancreatized milk. In most of these cases the infant had no fresh food; a few were given a small amount only. Of the cases reported by American writers, I find a few in which the infant had received a small amount of breast milk, but usually it had been weaned, and the diet in the most of the cases was some patent food or condensed milk. An interesting question is this: Can sterilized or pasteurized milk cause this disease? Upon this subject I find a difference of opinion. Cheadle, Ashby and Wright in England, and Osler in this country, say that it can. Professor Rotch, of Boston, and Professor Northrup, of New York, say there is no evidence to prove that it can. All writers agree that the real cause of scurvy is a lack of fresh food. Cheadle believes this lack of freshness to be due to the want of organic acids. The following English writers on children—Ashby and Wright, Carmichael, Eustace Smith, Goodhart, Donkin, and Angel Money—all speak of scurvy as a complication of rachitis, and call it scurvy rickets. It is no doubt true that rachitis is much more prevalent in England than in this country and consequently that the two diseases are frequently associated. Of the cases collected by Northrup, scarcely one-half presented any symptoms of rickets. Professor Rotch states "that his own individual experience has been derived from fifty or sixty cases, and that not more than a dozen presented any symptoms whatever of rickets." Now, as there are many cases of rickets presenting no evidence of scurvy, and, in this country at least, many cases of scurvy presenting no evidence of rickets, it is clearly a misnomer to call the disease scurvy rickets. Both are diseases of nutrition; both have for their cause improper food, and they are often associated, but each has its distinct clinical course. An infant reared on food lacking in fats and proteids will likely develop rickets. Now, let the food lack in freshness as well, and scurvy may manifest itself. On the other hand, a food abundant in fats and proteids will not cause rickets, but may, from lack of freshness, cause scurvy with absolutely no evidence of rickets. The two diseases are, therefore, often associated because of food defects, but they do not bear to each other the relation of cause and effect. Age is an important etiological factor, the age limits being at one extreme four months and at the other three years, almost all cases occurring between the ages of six and eighteen months, just the period when infants are kept on an exclusive diet. We might reasonably expect to find the disease among infants deprived of fresh air, sunshine, and wholesome environment. Frequently this is the case, but

¹ Read before the Nebraska State Medical Society, at Lincoln, May 20, 1896.

let it be remembered that a number of cases have been reported from the homes of the wealthy, where the infant has had every comfort that money could procure, everything needed for health except proper food. These are usually cases in which the infant has been reared on some patent food.

The clinical course of the disease is quite uniform. The precursory symptoms, lasting from four to six weeks, are as follows: anæmia, often associated with an earthy complexion; general and progressive muscular weakness; mental hebetude, the child being easily irritated; gastro-intestinal disturbances, usually diarrhœa, more rarely constipation, loss of appetite, and frequently vomiting of food. Thus far there is nothing significant except perverted nutrition. Among the symptoms especially peculiar to scurvy are "pain on handling and excessive tenderness, especially on moving the limbs;" when approached the child cries from fear of being touched; swelling of one, or more rarely of both thighs; more rarely still, swelling of one or both arms. The swelling is fusiform in shape.

Purpura is noted in a number of cases; hemorrhages into the subcutaneous connective tissues, frequently about the eyes; in some cases hemorrhages from the bowels; in a few cases hæmaturia. The condition of the mouth is peculiarly significant. When teeth are present the gums are swollen and purple; frequently they become ulcerated and bleed freely, so that the breath becomes fetid. In some cases there is enormous tumefaction of the gums, to such an extent that they protrude from between the lips. Before the eruption of teeth the swelling of the gums is slight and there are frequently ecchymotic patches in the mouth. The surface over the swollen extremities is not hot, or feverish, as in inflammatory swellings. It will be noted that all of these essential symptoms have their origin in hemorrhage. The subperiosteal hemorrhage causes the swelling of the extremities and is usually greater in amount just above the epiphysis. This is the most prominent anatomical change. "The diagnosis is to be made from acute rheumatism, purpura hemorrhagica, rickets, syphilis, and spinal paralysis" (from Professor Rotch). In rheumatism the pain and swelling are about the joints; in scorbutus in the shafts of the bones. Rheumatism comes on acutely with fever and hot skin; scorbutus after weeks of failing health, with little fever. Purpura hemorrhagica is often seen in cases of scorbutus, and no doubt, as Professor Northrup says, many cases of scorbutus have gone astray under that name; but in purpura the osseous symptoms and the swollen gums together with the history of the case should lead to a correct diagnosis. In spinal paralysis the pain passes away after the initial symptoms, and tenderness, so markedly prominent in scorbutus, is absent. The onset of spinal paralysis is almost always acute without premonitory symptoms. In rickets the onset is slow, but the enlargement is in the ends of the bones. Pain on handling is very rarely noted in rickets. When scorbutus develops in a rickety child, we have, in addition to the ordinary symptoms, the fusiform swelling of the extremities and the stomatitis. Hereditary syphilis usually manifests itself by the third month; scorbutus almost never before the sixth month. In syphilis the nasal symptoms, mucous patches, and skin eruptions are usually distinctive. The prognosis, when the disease is properly treated, is good. Cheadle has seen but one fatal case out of nearly fifty. The most important fact concerning the disease is that when its true nature is recognized, it promptly yields to treatment, but for want of proper treatment many cases have gone on to a fatal termination in spite of all drug treatment.

Pathology.—The essential character of scurvy consists in perverted nutrition. Owing to the lack of

some element of food the processes of secondary assimilation are perverted and the mysterious harmony existing between the blood and tissues is deranged. No blood changes, either microscopical or chemical, have thus far been discovered. A careful post-mortem examination by Professor Northrup revealed numerous hemorrhages beneath the periosteum of the shaft of the femur, dark, disorganized blood in the stomach, infiltrations of blood in the cellular tissues; no inflammatory changes in either the periosteum or bone were disclosed by microscopical examination, and no evidence of suppuration. In one post-mortem reported by Cheadle, in addition to the subperiosteal hemorrhage there was free blood in the air vesicles, this being the immediate cause of death. In the post-mortems reported by Barlow, the subperiosteal hemorrhage was the most important fact stated. No mention is made of the pathology of scorbutus by either Whitehead, Green, or Ziegler, and but brief mention of the disease in adults by Delafield and Prudden. The subject of treatment will be mentioned in the report of the following case recently under my care:

Infant, male, born November 30, 1894. During the first four weeks of life it nursed at its mother's breast, but, the supply of milk failing, it was put on a diet of modified cow's milk. On June 7, 1895, when six months old, it was taken with acute enterocolitis, recovering in a few days. July 17th it had the second attack. During this period it was still on modified cow's milk, but on the latter date was placed on an exclusive diet of a dry patent food. There was no further diarrhœa, but, on the contrary, marked constipation. During the month of August the infant gradually failed in strength, and, owing to absorption of subcutaneous fat, the skin lay in loose folds. It gradually became more pale and anæmic, cross and fretful, sleeping only for short periods of time. About September 1st I again saw the baby. The mother said it would cry when taken up, but would lie for hours upon the bed when undisturbed. It now had two teeth; its mouth was sore and the gums were red and swollen. September 29th I again saw the child. It still cried when touched or when approached; the right leg kept motionless; the thigh was evidently swollen and very tender to the touch. The sore mouth persisted in spite of treatment by chlorate of potassium and other mouth washes. The gums were now so swollen as almost to cover the two teeth and bled when touched. It now became apparent that this was something more than marasmus. The true scorbutic nature of the case finally dawned upon me, and on October 1st I placed the infant on a mixture of milk, cream, and sugar of milk, giving it three ounces every two hours; also the expressed juice of half a pound of rare steak each day and the juice of one large orange daily. I gave it castor oil daily, as the bowels were still constipated. The only medicine given was a simple elixir of pepsin. Three days after the beginning of this treatment the infant was markedly improved. In ten days it could be taken up without any evidence of pain. The swelling of the thigh rapidly subsided. By November 1st, thirty days after the beginning of treatment, the little patient had almost entirely regained his health and strength, excepting that he did not attempt to walk until eighteen months of age. This patient lived on sterilized milk for five months, when the bowel trouble commenced, and then on an exclusive diet of desiccated food for two and a half months, when well-marked scurvy symptoms developed. There were absolutely no symptoms of rickets in this case. I believe the symptoms and treatment proved beyond doubt that this was a case of true infantile scorbutus.

OXYGEN IN THE TREATMENT OF ACUTE CAPILLARY BRONCHITIS.

BY JOHN L. CORISH, M.D.,

BROOKLYN, N. Y.

ACUTE capillary bronchitis in the newly born is a disease which is more common than might be supposed. Many if not nearly all cases of acute broncho-pneumonia take their origin from an attack of acute capillary bronchitis. By some authors these conditions are treated as if they were different stages of the same disease. It is absolutely essential that the catarrhal condition of the capillary tubes should be recognized as a distinct and separate order, and though it may furnish the conditions for a subsequent attack of broncho-pneumonia, yet it can be treated separately, successfully, and practically. The catarrhal condition may arise from change of temperature, exposure, or introduction of noxious gases, or it may be secondary to a primary acute catarrhal rhinitis and pharyngitis. Another cause is found to be the imperfect closure of the foramen ovale. In the latter class the acute capillary bronchitis is secondary to the engorgement of the capillaries with semi-venous blood. The symptoms present all the characteristics of the class of diseases in which there is not sufficient accommodation for obtaining a normal amount of respiratory air—viz., œdema glottidis, croupous laryngitis, the second stage of pneumonia, etc.—except that we have the capillary râles in abundance at the beginning of the catarrhal affection. The dyspnoea is noticeable from the beginning and increases rapidly. The number of respirations rises to 60, 70, or even 80 per minute. The temperature may run up half a degree in the early stage, only to fall to a subnormal condition toward the end. The pulse, at first rapid and throbbing, finally becomes thread-like. Dulness on percussion, such as is present in broncho-pneumonia, cannot be obtained at any time during the attack. In this disease the pathology is easily understood. To be brief, the lining membrane of the lobules becomes engorged with blood and a mucous secretion is thrown out. This collects in the capillary tubes and forms a barricade, so to speak, by means of which inspired air is prevented from penetrating into the lobules. The residual air in the lobules becomes absorbed by the blood and a vacuum is created. The lobules, being unsupported by the pressure internally, collapse, a result known as atelectasis.

The physiological results of the obstruction are the collapse of the lobules; the inability of the blood to extract sufficient oxygen for the bodily requirements; the efforts of the different sets of direct and accessory inspiratory muscles to overcome this condition; the resulting general cyanosis; the indifference with which the child regards the partaking of nourishment, its whole time being occupied in its efforts to obtain air; the gradual exhaustion from want of nourishment and overexertion of muscles; and, finally, the easy death from asphyxiation. How have we treated these conditions when they have been met? Have we treated them symptomatically? Yes. We have been taught to keep the alimentary canal freely open. We have given our great standby, the ammonium salts, as a stimulant and expectorant, and whiskey, also, as a cardiac stimulant. The child bears the ammonia very well in this class of cases. We have used counterirritants to the chest wall. We have ordered the breast to be continued, but the child is unable to perform the function of suction and enforced respiratory efforts at the same time. When there is temporary relief the child obtains an oversufficiency of food, which results in the usual vomiting, followed by passages of undigested or decayed cheese and by various sequelæ. Then these ad-

ditional symptoms must be promptly met. The child relapses into its cyanotic condition, but this time to a greater degree. The physician sees that his cardiac stimulants are having but little effect; the expectorant preparations are of scarcely any avail; all hope of a favorable prognosis has passed.

The following case is an example of one continually met with by the experienced physician in his private practice. On January 5, 1896, I was called to attend a child, whom I delivered three days previously. There were no malformations, and from careful examination I was satisfied of the perfect closure of the foramen ovale. During the evening an acute capillary bronchitis had set in, following an acute catarrhal rhinitis which had existed for twenty-four hours previously. The temperature of the lying-in room varied at times, ranging from 68° to 82° F. The rectal temperature of the child was 99° F.; respiration, 60; and pulse, 150, strong and full. I cleared the nasal passages and ordered one-fourth grain of ammonium carbonate, together with five drops of spiritus frumenti, every hour.

January 6th, 8 A.M.—Respiration, 72, bronchial and shallow. The child refused nourishment. The temperature was 97.8° F. Limbs cold. A general cyanosis had set in; the capillary tubes were filled with mucus, and an acute conjunctivitis in the left eye was also noticed. At 9 P.M. I met Dr. Brandt, of Brooklyn, in consultation. We came to the conclusion that the treatment already adopted should be continued and that the doses should be increased. Accordingly, we gave one-half grain of ammonium carbonate and ten drops of spiritus frumenti every hour. Toward morning there was some improvement in the frequency of the respiration and the cyanosis was less marked. The pulse dropped to 140, stronger; respiration, 50; temperature, 98° F. The stools became greenish and of a mucous character, to correct which a warm enema of boric-acid solution was used occasionally.

January 7th, 8 A.M.—Respirations, 76; cyanosis very marked. The alæ of the nose were dilating, in unison with the other respiratory movements. Abdominal breathing marked. Temperature, 97.6° F.; pulse, 160, thread-like. The ammonium carbonate was increased to one grain every half-hour, which dose the child stood well, with but slight vomiting of mucus. The child had refused to nurse for the past twenty-four hours. Beef extract and whey, to which sweet butter and milk sugar had been added, were injected into the bowels as nourishment.

The case became so desperate that at 3 P.M. I obtained a cylinder of oxygen compound, one hundred and eighty-five pounds pressure. A mouthpiece to be attached to the wash bottle was constructed of an ice bag, cut in such a manner that it could be tightly placed over the vault of the cranium and beneath the chin. Into this was inserted the outlet tube of the wash bottle, fastened with ordinary rubber elastic bands. This rudely constructed affair was placed over the child's face, the child lying in the dorsal position on a table, with the head extended well back. The oxygen mixture was at first applied under a slight pressure. The respirations decreased in rapidity, they became deeper, and in a short time the color of the integument changed from a blackish blue to a normal flush. Then the child cried, something it had not done for forty-eight hours previously. The administration of the mixture was discontinued at the end of three minutes. The respirations had dropped to 42; pulse, 140, full and regular; and the temperature rose to normal. At the end of an hour the respirations rose to 70, cyanosis returning. The oxygen mixture was re-applied, with results similar to those obtained in the former trial, except that the time was shortened to two and one-half minutes. All through the night the mix-

ture was given, with increasing intervals between applications, but with the pressure gradually increased up to one-half an atmosphere. It was observed by the mother, and called to my attention, that immediately after the inhalation of the gas the child cried and took to the breast like a starved youngster, something it had had no time to do previously, as it was too busy with the more important object of obtaining air. From this time on, only the natural nourishment was necessary.

On January 8th the total number of applications given was four, after each of which the child nourished naturally. Bismuth and irrigation allayed the intestinal indigestion. The last application of the gas was given at 3 P.M., and it was at this point that the child was anesthetized by the oxygen, owing to the enormous absorption. The pressure used was one-half an atmosphere, sustained for three minutes. (For what followed, see article in the *MEDICAL RECORD* of September 12, 1896.)

Auscultation of the lungs immediately afterward showed total absence of capillary obstruction, there being present only a few scattering bronchial râles, which from that time grew fainter in character and on January 11th finally disappeared. On January 9th, the day after the oxygen was discontinued, the conjunctivitis of the left eye assumed a purulent character. The right eye has not been affected up to this date (February 24th), except by an acute catarrhal conjunctivitis. An important question for the oculist to consider is: Did the application of the oxygen retard the appearance of the purulent inflammation of the right eye and render the left eye immune?

What difficulties are encountered in this disease, and how shall we meet them satisfactorily? The obstruction of the mucus in the tubes must be removed. The child cannot accomplish this, being unable to inspire sufficiently deep. A pressure of one-half an additional atmosphere will accomplish this. The oxygen, restoring the capillary engorgement to a normal character, will prevent the formation of additional mucous secretion. The collapse of the lobules cannot be remedied by any means brought to bear through the general circulation, but it can by means of the pressure applied. The heart action, which is in a very feeble condition, must be sustained by stimulants internally administered. But oxygen, as is well known, by restoring the capillary circulation to its most favorable condition for normal movements, acts indirectly, but with no less a degree, certainly as powerful, as a cardiac stimulant. The fact that the child refuses nourishment is evidently not because it has no desire in that direction, but it is hampered very greatly in its demand for air by the generally accompanying acute rhinitis, and also by the additional obstruction which the nipple necessarily accomplishes in addition.

As to the final treatment adopted in this case, what physiological results were obtained? The oxygen, being introduced into the system in greater abundance, combated the cyanosis by relieving the reflex vasomotor irritation. The production of secretion becomes thereby lessened. The secretion already in the tubes was forced deeper into the lobules. The collapsed condition of the lobules was remedied by the increased pressure, they being distended to their greatest capacity, and gradually, a normal condition being re-established, this latter action being purely mechanical. After the first application of the oxygen mixture, the child is in a state similar to that of one who has passed through its first night of an attack of false croup. It will go back to its former condition, or nearly so, because we have given only sufficient to maintain the balance of supply and demand for an hour or so.

Some one asks, Will you have to apply oxygen every

time the child becomes cyanosed? Yes. After the child has received sufficient to enable it to nurse, push your treatment. Reapply the gas under increased pressure and expand the lungs to their extreme capacity. The atelectatic condition disappears and the lungs are better able to do normal work. If the oxygen is applied with still further pressure and the child allowed to inhale this alone, for a period of from two to three minutes, the system becomes thoroughly saturated, the breathing ceases, but the pulse is still sustained normally and there is a temperature of 99° F. The integument assumes a rosy hue and voluntary muscular movements cease. This state will last from five to seven minutes, during which time the child will recover a great part of the energy wasted in the diseased condition. When the superabundant oxygen stored up in the system has been used up in the bodily requirements, the respiratory movements will begin again as in the newly born. If it were only required to combat the cyanosis, I believe this could be done sufficiently well, temporarily, by inflation of the large intestine with the oxygen mixture. But the keynote to the treatment of acute capillary bronchitis is to expand the lungs to their fullest extent by pressure from within; to alter the character of the circulating fluid by giving oxygen; and to allow the respiratory muscles sufficient time to recuperate—all of which can be accomplished simultaneously by the administration of the oxygen mixture under pressure.

February 24, 1896.

THE CARE OF THE BREAST IN LACTATION.¹

By CHARLES ROSEWATER, M.D.,

PROFESSOR OF OBSTETRICS, CREIGHTON MEDICAL COLLEGE, OMAHA, NEB.

It may seem strange to some of you that I should bring before this society for its consideration a subject which, by many, is relegated to the domain of the nurse. But this is the very trouble with our medical societies. We spend hours, yes, whole sessions in the discussion of such subjects as laparotomy, hysterectomy, ectopic pregnancy, ovariectomy, or some wonderful but rare operation which perhaps not more than one out of a hundred of us is ever called upon to perform or even to consider; yet the subject of the care of the breast in lactation hardly ever occupies the attention of the members of our profession at their meetings. I dare say, however, that ninety-nine out of every hundred physicians are called upon almost daily for advice and counsel upon this subject, and upon that advice depends the happiness of an anxious mother and the welfare of a new-born babe, not to consider the comfort of an entire household. Many an infant dies during its first year on account of having been deprived of its natural food, when by careful and persistent attention at the right time the mother's breast might have been put and kept in proper condition to supply the food nature intended it should.

In the consideration of this subject the first question which naturally arises is: Does a healthy breast require any preparation for its utilization in nursing? Can we by some means or other aid the mother so that she will be better able to nurse her child? Is there anything which we can do during the latter months of pregnancy to improve the condition of the mother and her breast with special reference to the performance of the function of lactation?

I would answer, "Yes—in a large number of cases we can." In some cases, however, our services are unnecessary and undesirable. Just as many women can go through childbirth naturally and without any

¹ Read before the Omaha Medical Society, on June 9, 1896.

assistance without impairing their physical integrity or vitality, so can many nurse their children without any preparation or care directed toward the breast. This being the case, it is important for us to know when our services must come into requisition. What local or constitutional conditions might require correction by us to make the woman suitable as a nurse for her child?

It is hardly necessary to state that malignant tumors of the breast preclude nursing. It is in fact a great rarity for malignant tumors of the breast to develop during pregnancy, or for pregnancy to occur coincident with such tumors.

The presence of benign tumors of the breast does not necessarily contraindicate its use in nursing, for, while it is a fact that in a large number of such cases the tumors so affect the glandular structures of the breast that their secretion is impaired either in quality or in quantity, yet there have occasionally been cases in which the mammary gland itself was not affected in the least and its secretion continued to be fit for the child and of sufficient quantity. Hence in such instances each case must be considered individually, and no general rule can be laid down except perhaps that the mere presence of a benign tumor of the breast need not preclude nursing when the milk secretion is normal.

The condition of the nipple should next occupy our attention. When the nipple is flat so that the most arduous attempts to draw it out with a clay pipe, breast pump, or some similar instrument fail, lactation is of course out of the question. In many cases, however, in which the nipples appeared flat and useless, and the patients even claimed that other members of their family had been prevented from nursing children on account of similar disability, I have succeeded in making the breast quite serviceable by insisting on persistence in the efforts at drawing the nipple out by means of a clay pipe, these efforts being begun usually during the last month of pregnancy. If the nipple cannot be drawn out at all, the patient will be unable to nurse her child.

If the breast is flabby and secretes no milk, or only a very inferior article, it is far better to furnish the child other means of nourishment.

If the patient is suffering from serious constitutional disease, such as tuberculosis, intense anemia, or recent syphilis, it is better for her not to nurse her child. So also when she is suffering from some serious nervous disease, such as epilepsy, hysteria, etc.

In acute febrile diseases, as a rule, the breast ceases to secrete and lactation must of course be interrupted. Sometimes the interruption is only temporary, even though it may be of considerable duration, as in a case of puerperal fever which I attended several years ago, in which after convalescence was established, the secretion of milk returned and the child was again nursed by its mother after it had been nursed by its aunt for seven weeks.

Many nurses and even some physicians advise the use of astringent lotions, such as a solution of alum in whiskey and water to be applied to the nipples during the last month of pregnancy, so as to harden them and dull their sensibility. I have seen some cases in which this method of procedure seemed to me to result in greater tenderness and dryness of the nipples and finally in the development of fissures, so that I am not in the habit of advising it. It has been my practice to advise that the nipples be rubbed occasionally with vaseline or cold cream to render the skin soft and pliable. When the breasts through their turgidity become very tender, and especially when through clogging of the milk ducts a condition known as caked breast develops, gentle massage together with the application of a snug breast binder, which sup-

ports the breast and prevents it from hanging down, will be a great source of relief.

If the patient has a history of having lost children previously through not having had sufficient good milk for them, she should be put on a tonic toward the end of pregnancy—some preparation especially adapted to improve her general health. Just what preparation should be used in each individual case will depend upon the circumstances.

How soon after childbirth should a mother nurse her child? This depends upon the mother's physical condition and the severity of the labor through which she has just passed. As a rule, a woman may be allowed to nurse her child as soon as she has obtained her first good rest after childbirth. If she has gone through a severe labor, complicated perhaps by severe hemorrhage, it is well to give her plenty of rest, at least twelve hours before putting the child to the breast. Before the child is put to the breast the nipple should be carefully washed, and the child's mouth also. If the nursing is accompanied by severe local pain about the nipple without there being any excoriation or fissure noticeable, then application of a weak solution of nitrate of silver (five to ten per cent.) to the nipple after nursing will so toughen the cutaneous surface and dull the sensitiveness of the parts that the next nursing will be less painful. Sometimes the temporary use of a nipple shield will tide the patient over this period of greatest tenderness, but often children will not nurse through such a shield. Persistence in the efforts directed in this channel will, however, as a rule, be crowned by success, but sometimes leads to maceration of the epithelial covering of the nipple. This condition, which is extremely painful, may also develop when the child is allowed to nurse too often and too long. The feeding of infants at the breast should occur at regular intervals, not oftener than every two or three hours during the daytime and once or twice during the night.

In cases in which the nipples become very sore and tender I usually succeed in overcoming the difficulty by applying a powder of tannic acid or bismuth after the child has nursed and the nipples have been washed. And right here comes another factor largely responsible for the sore breast—the macerated nipple, I mean—that is, the constant moistening of the nipples from the milk oozing out. This can be obviated if the patient will wear some absorbent covering, such as cotton batting, over the nipples at times when she is not nursing the child. The parts should be kept dry between the nursings.

In some cases by the time the physician is called, a fissure has developed at the root of the nipple, causing the patient excruciating pain whenever her child nurses, and so exhausting her strength as frequently to lead to high fever and great prostration. And yet a very little treatment is needed to successfully overcome this difficulty. After cleansing the parts thoroughly I usually cauterize the fissure with nitrate of silver in stick, then neutralize and wash off the superfluity of caustic with a solution of common salt and apply tannic acid dry on the nipple when a state of maceration of the nipple exists, or a glycerole of tannin when the epidermis seems to be too dry. In these cases it is also well for the patient to rest the sore breast for from eight to twelve hours at a time. Usually one cauterizing, such as the above, will suffice.

If, however, infection has already occurred from the fissure, a mastitis may develop, ushered in by a chill or succession of chills, followed by fever, pain in the entire breast and extending up into the axilla, hardening and tenderness of the breast, with usually some alteration of the milk secretion. The latter may be either entirely checked or greatly diminished and

deteriorated, but, no matter how this is, the breast should in such instances be put to rest completely by prompt cessation of nursing. Laxatives and quinine should be given and a firm breast binder applied. Cold applications may be applied with advantage in such cases when suppuration is threatened, but as soon as it is an established fact moist heat should be substituted for the cold, and as soon as pus can be reached it should be let out through a free incision, made in a direction radiating from the nipple and at as low a point on the breast as is consistent with easy access to the pus. From this on, the case should be treated on surgical principles, drainage being necessary in some cases, while curetting and firm packing with antiseptic dressings are necessary in others.

When it is desirable to dry up the secretion of the breast the use of an atropine ointment (one grain to the ounce) or belladonna ointment (fifteen grains to the ounce) has been strongly recommended, but in many if not all cases the simple application of a snug binder together with cessation of the use of the breast is all that is necessary. The breast, not being used, gradually stops secreting milk. It is well in these cases also to give Epsom salts or some other cathartic to carry off the superfluous liquid by other channels.

ARE SANATORIUMS FOR CONSUMPTIVES A DANGER TO THE NEIGHBORHOOD?

By S. A. KNOPF, M.D. (PARIS AND BELL, N. Y.),

NEW YORK,

FORMER ASSISTANT TO PROFESSOR DETTWEILER, FALKENSTEIN SANATORIUM, GERMANY.

AFTER the publication of my French thesis on sanatoriums for consumptives,¹ in which I endeavored to make a strong plea for such special institutions as one of the best means of curing and preventing pulmonary tuberculosis, I was surprised to hear several of my medical brethren, some of them of high standing, express their disapproval of housing a large number of tuberculous patients in one institution. A few even thought my ideas almost dangerous. The laity in Europe were, of course, still more pronounced in their prejudices, opposing the establishment of sanatoriums for consumptives on the ground that their proximity would prove a source of infection.

To set such fears at rest, I published an article in the *Revue de la Tuberculose* for December, 1895, entitled "Les Sanatoria de Phthisiques, sont ils un Danger pour le Voisinage?" Since my return to the United States I have learned that the same prejudices exist here, which, I am sorry to say, are often shared or even advanced by medical men. To convince them of the absolute harmlessness of the vicinity of a properly conducted sanatorium for consumptives is the object of this article.

In my communication to the *Revue de la Tuberculose*, I mentioned some of the most surprising views expressed by medical and civil authorities, and cited one or two instances which, as they illustrate the case in point, will perhaps bear repeating.

For years it had been the object of some philanthropists in Frankfort-on-the-Main, who have in their vicinity that excellent institution for consumptives in Falkenstein, to open a similar one for the poorer classes. At last their wishes were realized, a building was procured, and things were in running order. Professor Dettweiler had kindly consented to act as physician-in-chief, and a house physician had been appointed. But an aristocratic lady, living a few miles from there, objected to her new neighbors. As

she did not wish to leave her elegant country residence, she offered to buy the house which had been made a sanatorium for far more than it was worth, on condition that the patients should be moved much farther away. The offer was accepted, and to-day the poor consumptives of Frankfort have at Ruppertsheim a large, handsome, comfortable structure, better located and three times as large as the original one. But it is far from the home of the baroness.

Near Vienna existed a place which had been known for years as a health resort for consumptives and persons suffering from similar troubles. Thanks to the efforts of a distinguished professor and specialist in phthiseo-therapeutics and the funds given by a wealthy philanthropist, it had been decided to found a sanatorium for poor consumptives, under the direction of this professor, in the resort mentioned. But the authorities of the community raised such an outcry at the prospect of having this institution in the midst of them, fearing it would drive away the class of wealthy patients who had come there for so long, that the professor, not wishing to go where his sanatorium would not be welcome, chose another locality.

They thought they had done a wise thing; but soon the wealthy patients, thinking that the new place must possess superior advantages to have been chosen by so celebrated a specialist for his institution, began to flock thither; and the old resort, so favored for years, found itself quite deserted.

Here in the United States one will find the authorities of small communities opposing the establishment of a sanatorium for tuberculous patients, but no objection would be made to a home for consumptives, especially if under church supervision. Most of these institutions are the work of the Episcopal Church. I cannot speak too highly of the laudable efforts of these noble men and women to provide a place of rest for poor consumptives, but I have recently visited a few of these "homes," and I must confess that they seem to me a dangerous experiment. There is never a house physician; the visiting physician comes but rarely, and then only to see the most urgent cases. The direction is in the hands of the brother or sister superior or matron. What results in regard to prophylaxis and treatment can be obtained under such conditions? To me it seems an illusion to think that any notable good can be accomplished in such a "home" without a physician. Consumption is a curable disease, and therefore tuberculous patients should be treated and not kept. The excellent results obtained in sanatoriums for consumptives are due to the constant medical supervision and the personal training of the patient. The physician presides at the table, directs the rest cure in the open air, the breathing exercises and graduated walks, the hydrotherapeutic applications, and the many other curative and preventive measures, the *ensemble* of which constitutes the real treatment of pulmonary tuberculosis.

To watch that there may never be any relaxation in regard to the care with the expectoration requires more than the gentle rule of a sister superior. Still, such "homes" seem to be welcome in communities where sanatoriums are shunned, although one is really safer from infection in a properly conducted sanatorium for consumptives than anywhere else.

The most important factors in imparting the disease are the expectoration, the saliva, and other secretions. In a properly conducted sanatorium patients never expectorate except in a receptacle provided for the purpose, a spittoon or pocket flask. Those in bed and too weak to make use of the spittoon are provided with moist rags, which are burned immediately after use. The expectoration and other secretions are destroyed before they have a chance to dry and do harm. Napkins and table utensils are boiled or disinfected

¹ "Les Sanatoria. Traitement et Prophylaxie de la Phthisie Pulmonaire." Par le Docteur S. A. Knopf, Paris, 1895; George Carré, éditeur.

after each meal. Besides this, a scrupulous cleanliness is observed in all rooms, and the furniture is so arranged that a thorough disinfection may be easily carried out.

Repeated microscopical and bacteriological examinations of the dust taken from the rooms of such sanatoriums have proved it to be practically free from bacilli. At Saranac Lake, the great American sanatorium, none of the twenty to twenty-five attendants have ever developed tuberculosis. The contraction of the disease by physicians, nurses, or employees is almost unknown in these institutions.

But the effect of such sanatoriums upon their surroundings is not a matter of conjecture or of opinion. We can bring experience and statistics to our help. In Goerbersdorf, the largest and oldest sanatorium for consumptives in the world, through which some two thousand patients pass every year, the mortality from tuberculosis among the people of the neighboring village has decreased in a wonderful degree since the establishment of the institution. Not only has the sanatorium done no harm to the surrounding population, but it has done good, through the example set before the village people by the patients and the sanitary regulations, which direct all attention to the destruction of the bacillus. To uphold these statements I will repeat from my thesis the official statistics of the village of Goerbersdorf for a hundred years:

DEATHS FROM PHTHISIS PULMONALIS.

1790-1799.....	14	1840-1849.....	6
1800-1809.....	5	1850-1859.....	7
1810-1819.....	9	1860-1869.....	4
1820-1829.....	9	1870-1879.....	5
1830-1839.....	8	1880-1889.....	5

These statistics become still more valuable when one considers that the population of Goerbersdorf has doubled in the last twenty-five years.

Recently Dr. Nahm has compiled the statistics of the village of Falkenstein. Here also the mortality from pulmonary tuberculosis has been reduced from 18.9 per cent. before the establishment of the sanatorium, to 11.9 per cent. after it was opened. I will give the statistics of Falkenstein in full, as they were published by Dr. Nahm:¹

DEATHS FROM PHTHISIS PULMONALIS.

Before the Establishment of the Sanatorium.	After the Establishment of the Sanatorium.
1856-1858..... 17.2 per 100.	1877-1879..... 17.0 per 100.
1859-1861..... 7.7 "	1880-1882..... 14.6 "
1862-1864..... 22.6 "	1883-1885..... 6.0 "
1865-1867..... 14.0 "	1886-1888..... 5.0 "
1868-1870..... 16.7 "	1889-1891..... 13.9 "
1871-1873..... 21.0 "	1892-1894..... 15.1 "
1874-1876..... 33.3 "	

It is the duty of the profession to enlighten the public and the civic authorities on the question of such institutions. Europe has many advocates of the establishment of sanatoriums for consumptives. Foremost among them are Grancher and Letulle, of Paris; Leyden, of Berlin; Schrötter, of Vienna; von Ziemssen, of Munich; and Weber, of London.

In the United States the pioneer work in this line has been done by Bowditch, of Boston, and Trudeau, of Saranac Lake. They both have visited the sanatoriums abroad, especially the one at Falkenstein, and were much impressed with the beneficial results obtained by the hygienic and dietetic treatment in these "closed" establishments.

Last year, Dr. Guy Hinsdale, of Philadelphia, read a most interesting article at the meeting of the American Climatological Association, entitled "Recent Measures for the Prevention and Treatment of Tuberculosis,"² wherein he set forth the necessity of sanatoriums, especially for the poorer classes.

In the MEDICAL RECORD of December 28, 1895, Dr. Irwin H. Hance, formerly assistant to Dr. Trudeau, published the account of an interesting series of experiments with dust taken from various sources (hospitals, sanatoriums, etc.), showing how free from danger one is where the proper precautions are taken in regard to the expectoration, and how little reason there is to fear the proximity of a sanatorium for consumptives.

At this year's meeting of the American Climatological Association, Dr. Edward O. Otis, of Boston, read a very instructive paper, entitled "The Sanatorium or Closed Treatment of Phthisis."¹ In it he speaks of the fears that sanatoriums may be a source of contagion as misconceptions, and considers such properly conducted establishments one of the best means of curing pulmonary tuberculosis and of combating the spread of the disease. Well-conducted sanatoriums for consumptives are not centres of infection; but, on the contrary, places where the tuberculous patient is the most free from the danger of autoinfection, and where there is the least chance of his communicating his malady to others.

—*La Riforma Medica.*

Diffuse Bronchitis in Children.—Dr. Renault believes that a simple and harmless method consists in giving a bath at 100.4° F. for seven to eight minutes every three or four hours, until the temperature taken three hours after the last bath has reached 102.2° F. After a third or fourth bath the fever falls without rising, and the disease becomes a slight bronchitis, without even becoming capillary. Quinine sulphate is given as a general tonic.—*Journal des Praticiens*, 1896, No. 13, p. 205.

Osteomyelitis and Immunizing Experiments.—

Dr. Canon (*Deutsche Zeitschrift für Chirurgie*, xlii., No. 1) draws the following conclusions from a series of experiments: (1) The presence of streptococci in osteomyelitic processes is to be regarded as dangerous. (2) Staphylococcus osteomyelitis is by far the most frequent. (3) Osteomyelitis is to be considered as a staphylococcus pyæmia of the developing period of life. (4) It is possible to immunize animals against a staphylococcus infection by the aid of blood serum from persons just recovering from a staphylococcus disease.

Kidney Wounds.—Dr. Trimble (*Maryland Medical Journal*) says: 1. All kidney injuries are to be considered as serious until proved otherwise. Never sit quietly by waiting for symptoms to develop in order that a diagnosis may be made. When in doubt, explore the kidney; the danger to the patient is not increased by an aseptic operation. 2. In all kidney wounds and wounds in the region of the kidney, the kidney should be examined through a large incision. In serious wounds of the kidney immediate operation is the only thing that will save the patient. The lumbar incision, when it will answer all the requirements of the case, is to be preferred to a laparotomy.

Chorea.—Dr. E. De Renzi (*Gazzetta degli Ospitali e delle Cliniche*, 1896, No. 29) has made use of eserine, antipyrin, salol, and ether spray along the vertebral column, but he places his confidence in only three remedies: (1) Absolute rest, the patient being placed in a dark room and avoiding all external excitation whatever. (2) The ascending electrical current along the spinal cord—the best results with a gentle current progressively increased. (3) Arsenic in large doses, commencing with twenty drops of Fowler's solution each day for children and double this amount for adults. The medicine should be continued after the chorea ceases, for the disease readily returns. The nutrition of the patient must be maintained, and good food and gymnastics are useful.

Time of Rupturing the Amniotic Sac in Labor.

—1. In multipara, rupture when os is fully dilated. 2. In primipara, delay until the soft parts are also dilated. 3. In cases of face and breech presentation, delay in rupturing the sac is best. 4. When the pelvis is small and the foetus large, delay rupturing. 5. In premature labor, with a dead foetus, rupture early. 6. Rupture the sac early when the membranes are unusually thick, tough, and unyielding. 7. When speedy delivery is demanded, rupture early and dilate with the fingers. 8. Rupture the sac when an excessive amount of amniotic fluid retards labor. 9. When version is necessary, and can be accomplished by bimanual manipulation, perform this operation before rupturing. 10. Remember that a dry labor is always to be deprecated; hence do not rupture at all, unless for good reasons and the case demands it.—*Atlanta Medical and Surgical Journal*.

Necessary Pocket Instruments.—An aseptic pocket case is a scientific absurdity. A good surgical knife, a stout pair of scissors, a sufficiently large and strong anatomical forceps, a large probe with a button at one end and an eye at the other, and possibly a piece of silk and a needle, are all the instruments that are really necessary. These may be carried in a neat canvas "folder" and the whole contained in a leather pocketbook. The instruments may be sterilized in a match flame and should be dipped in water while hot. The needle and silk may be boiled in a teaspoon over a match flame. Hemorrhage, even from quite a large vessel, may be checked by a silk suture. This device will nearly always take the place of the artery forceps.—*International Journal of Surgery*, June, 1896.

Urinary Examinations.—Dr. Lichty (*Medical News*) holds that 1. A continued low specific gravity must be looked upon with grave suspicion, until it can be proved beyond doubt that the kidneys are normal. 2. In nephritis, especially of the chronic interstitial type, it may happen that at times during the greater part of the disease the urine may contain no albumin that can be detected. 3. Casts may be present in the urine when it is impossible to detect any albumin by the usual tests. 4. Casts are very easily destroyed in the urine by bacteria during the process of fermentation, and unless the examination is made within an hour or two after the urine is passed, the failure to find casts does not prove the non-existence of nephritis. The urine should be more frequently examined, especially after sickness.

Pneumonia.—Dr. Scully (*Journal of the American Medical Association*, June 6, 1896) says: "Do not give alcohol in any form during any stage of the disease. I firmly believe that the use of alcohol has been the chief cause of the high mortality in recent years. Let the fever alone. The danger is not from the fever but rather the heart, and inasmuch as all of the recent antipyretics act as heart depressants, we should be

very cautious in their use in pneumonia. Stimulate your heart if necessary with digitalis, using a good reliable fluid extract, strychnine, or nitroglycerin. Oxygen should always be thought of when there is a tendency toward cyanosis. I have seen such excellent results follow its administration that I unhesitatingly say: Use oxygen in cyanosis and use it freely. I have never taken very kindly to cold packs or compresses, and have resorted to their use only in a few cases. Still in those cases where I have used the cold compresses I was pleased with the result. Poultices are disagreeable things at best, and only tend to worry and fatigue the patient."

Treatment of Red Nose.—Dr. Lassar (*Dermatologische Zeitschrift*) recommends scarification after various methods of exfoliation have failed. Fifteen to twenty per cent. resorcin paste is his favorite agent for producing the exfoliation. A superior method to scarification is acupuncture, done with forty points mounted on a solid disc one centimetre in diameter, worked by an electro-motor and stamping machine like that used in filling teeth; this method leaves only fine scars, and thousands of pricks very light and of desired depth may be made in a few moments. Consecutive treatment is rarely necessary. In rhinophyma, which Dr. Lassar considers as an adenocystic fibroma without epithelial proliferation, he removes the hypertrophied tissue by ablation or decortication, covering the surface with Thiersch grafts, or leaving it under iodoform collodion, which in many cases serves as well.

Relapse in Pneumonia.—Dr. Ruge describes the peculiarities of relapse in croupous pneumonia; he bases his remarks on a study of two cases under his observation, and seven reported by others. Between the two attacks there is an afebrile period of from four to fifteen days. During this time the subjective sensations are those of convalescence. The physical signs disappear, at least partially. The duration of the relapse varies from four to eight days. Usually the same part of the lung is affected as in the first attack. Ruge showed by an analysis of eighteen cases that such cases differ from wandering pneumonia, as this latter is of longer duration. Transition forms no doubt occur. The frequency of relapse in pneumonia is stated by various authors as from 0.18 to 0.45 per cent.—*Charité Annalen*, 1895, p. 184.

Charcoal.—Dr. Robert B. Wild, after a careful laboratory study of this drug, finds that the present antiseptic drugs are both more cleanly and more effectual and are not likely to be superseded by charcoal. Internally it has been used when there is undue decomposition of the contents of the alimentary canal, as in dilatation of the stomach, certain forms of intestinal indigestion, when the alimentary canal contains abnormal toxic substances, and in certain specific diseases presenting local lesions of the alimentary canal. The idea is gaining ground that the serious symptoms in these cases are due not so much to living organisms as to the formation of toxic substances. Charcoal is deserving of further trial from its action by oxidizing the chemical substances formed during abnormal decomposition, or the various toxins produced by pathogenic organisms. It is possible that the oxygen of the charcoal may modify the metabolic processes of the pathogenic organisms themselves and render them or their products less virulent. The power of this drug to remove alkaloids from solution is worth considering. It may prevent auto-intoxication from the alimentary canal, and may act as a laxative or remove mucus from the walls of the alimentary canal. It may be administered in doses of from two to six teaspoonfuls daily.—*The Medical Chronicle*, 1896, No. 6.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 3, 1896.

SCIENCE AND MEDICINE.

At the opening session of the British Association for the Advancement of Science, in Liverpool on September 16th, the president, Sir Joseph Lister, delivered an impressive address upon the mutual relations of scientific research and practical medicine.¹ The healing art in all its branches is becoming, he said, more and more based on science as distinguished from empiricism, and he proposed to depart from the usual custom of the presidents of the association of reviewing the progress of science during the year just passed, and to confine himself to the instancing of a few of the most noteworthy illustrations of this scientific basis of medicine and surgery. After a brief reference to the Roentgen rays, in the practical application of which he believed medicine had made but a beginning, he turned to the subject of anæsthesia, of which this is the jubilee year.

"That priceless blessing to mankind," he said, "came from America. It had, indeed, been foreshadowed in the first year of this century by Humphry Davy, . . . but it was not till, on September 30, 1846, Dr. W. T. G. Morton, of Boston, after a series of experiments upon himself and the lower animals, extracted a tooth painlessly from a patient whom he had caused to inhale the vapor of sulphuric ether, that the idea was fully realized. He soon afterward publicly exhibited his method at the Massachusetts General Hospital, and after that event the great discovery spread rapidly over the civilized world." The first operation in England under ether was performed by Robert Liston, in University College Hospital, and it was a complete success. Sir Joseph Lister witnessed this operation, and soon afterward saw the same surgeon amputate the thigh as painlessly by aid of chloroform, which was being advocated as a substitute for ether by Dr. (afterward Sir) James Y. Simpson. Concerning the respective merits of these two anæsthetic agents, the speaker thought that, when properly and carefully administered, chloroform was, on the average, safer than ether.

The next illustration of the debt practical medicine owes to science was taken from the work of Pasteur on fermentation. Cagniard-Latour, in France, and Schwann, in Germany, had independently discovered the yeast plant and had attributed the phenomena of

alcoholic fermentation to the growth of this micro-organism, but these views had been discredited by Liebig. Pasteur, however, proved that these earlier investigators were right, and he went further and showed that lactic acid and all other true fermentations are caused by micro-organisms. He also disproved the doctrine of spontaneous generation, which had been dislodged from various positions which it once occupied among creatures visible to the naked eye, and had taken its last refuge where the objects of study were of such minuteness that their habits and history were correspondingly difficult to trace.

But the most interesting portion of the address—most interesting to medical men, at least—was that in which Sir Joseph Lister spoke of his own great work and of the marvellous change it had wrought in modern surgical practice. He had been often asked to speak on his share in this matter before a public audience, but had hitherto refused to do so, chiefly because he felt an invincible repugnance to what might seem to savor of self-advertisement. But the latter objection now no longer existed, he said, since advancing years had warned him to rest from active labor. He had long been impressed with the greatness of the evil of putrefaction in surgery, for the inflammation preventing primary union was, he had become convinced, due essentially to decomposition of blood within the wound. He had done his best to mitigate this by scrupulous cleanliness and the use of various deodorant lotions, but to prevent it altogether appeared hopeless in face of Liebig's doctrine that its primary cause was the atmospheric oxygen. "When Pasteur had shown that putrefaction was a fermentation caused by the growth of microbes, and that these could not arise *de novo* in the decomposable substance, the problem assumed a more hopeful aspect. If the wound could be treated with some substance which, without doing too serious mischief to the human tissues, would kill the microbes already contained in it and prevent the future access of others in the living state, putrefaction might be prevented, however freely the air with its oxygen might enter."

He had heard of carbolic acid as having a remarkable deodorizing effect upon sewage, and determined to try it in compound fractures. He applied it undiluted to the wound and "had the joy of seeing these formidable injuries follow the same safe and tranquil course as simple fractures, in which the skin remains unbroken." But there was another and unexpected result of this application. Portions of tissue which had been killed by the violence of the injury were no longer thrown off as sloughs, but were absorbed and replaced by living tissue. This suggested the use of animal ligatures with all its manifest advantages. It was soon found that diluted carbolic acid would do as well as the pure acid, and gradually the truth was borne in upon him that the elaborate precautions against the access to the wound of the living atmospheric dust, which lead to the early employment of the carbolic spray, were unnecessary. Experiments showed that the blood was able to dispose of the attenuated forms of microbes existing in the air, and that it was only the grosser forms of septic mischief

¹ Science, September 25, 1896.

that surgeons had to dread. He had hinted, at the London Congress, in 1881, that it might eventually be found possible to disregard altogether the atmospheric dust, and nine years later, at the Berlin Congress, he brought forward what he believed to be absolute demonstration of the harmlessness of the atmospheric dust in surgical operations. "This conclusion has been justified by subsequent experience; the irritation of the wound by antiseptic irrigation and washing may therefore now be avoided, and nature left quite undisturbed to carry out her best methods of repair, while the surgeon may conduct his operations as simply as in former days, provided always that, deeply impressed with the tremendous importance of his object, and inspiring the same conviction in all his assistants, he vigilantly maintains from first to last, with care that, once learnt, becomes instinctive, but for the want of which nothing else can compensate, the use of the simple means which will suffice to exclude from the wound the coarser forms of septic impurity." In speaking of the various antiseptic materials which have been employed and their modes of application, he reiterated his well-known belief that carbolic acid, by virtue of its powerful affinity for the epidermis and oily matters associated with it, and also its great penetrating power, is still the best agent at our disposal for purifying the skin around the wound.

Leaving surgery, the speaker directed the attention of his hearers to the microbic theory of disease. He did not believe that we could look forward with anything like confidence to being able to see the *materies morbi* of every infectious disease, for it is not improbable that the micro-organisms of some diseases are too minute ever to become visible to man, even by the aid of the most powerful microscope; but he affirmed that it can no longer be doubted that such parasites are really the causes of all this class of diseases. Once the cause of a disease has been ascertained, the indications for treatment are obvious, even though they cannot for various reasons be at once met. Sir Joseph reviewed the progress which had been made in this direction and made a profession of faith in the principles of orrhoterapy. Concerning the antitoxin treatment of diphtheria in particular, he said that there are certain cases of so malignant a character from the first that no treatment will probably ever be able to cope with them, but it seems probable that, taking all cases together, Behring's hope that the mortality may be reduced to five per cent. will be fully realized when the public becomes alive to the paramount importance of having the treatment commenced at the outset of the disease.

Finally Sir Joseph Lister instanced the discovery by Metchnikoff of the protection against pathogenic micro-organisms afforded by the white corpuscles of the blood. He believed phagocytosis to be "the main defensive means possessed by the living body against the invasion of its microscopic foes," for, while the power of the system to produce antitoxic substances to counteract the poisons of the microbes is doubtless of great importance, it is inoperative in those cases in which animals enjoy a natural immunity against certain diseases. Here the sole defensive agency seems,

he said, to be phagocytosis. This theory of phagocytosis was ingeniously appropriated by the speaker to explain the fact, which had been discovered in his own field of antiseptic surgery, that the dust of the atmosphere might safely be disregarded in operations. It also seemed to afford a clear explanation of the healing of wounds by first intention under circumstances before incomprehensible. "This primary union was sometimes seen to take place in wounds treated with water dressing, that is to say, a piece of wet lint covered with a layer of oiled silk to keep it moist. This, though clean when applied, was invariably putrid within twenty-four hours. The layer of blood between the cut surfaces was thus exposed at the outlet of the wound to a most potent septic focus. How was it prevented from putrefying, as it would have done under such influence if, instead of being between divided living tissues, it had been between plates of glass or other indifferent material? Pasteur's observations pushed the question a step further. It now was: How are the bacteria of putrefaction kept from propagating in the decomposable film? Metchnikoff's phagocytosis supplied the answer. The blood between the lips of the wound became rapidly peopled with phagocytes, which kept guard against the putrefactive microbes and seized them as they endeavored to enter." But if phagocytosis could guard the system against septic microbes in so concentrated a form, it could hardly fail to prevent infection by the attenuated forms existent in the air.

THE KNEIPP CRANKS.

THAT portion of the community accustomed to view even novelties from a common-sense standpoint was more than surprised at the permission recently granted the followers of a notorious quack to walk bare-footed on the lawns of Central Park. It was looked upon quite naturally as a dangerous precedent for any set of cranks that might desire to foist absurd notions upon any community on the plea of equal rights and individual liberty. It is quite true that only a secluded portion of the park was delivered to them at certain restricted times, but the principle of recognition of the claims of these self-styled health missionaries was as effectually demonstrated as if every public square were placed at the disposal of their nonsensical antics. It was the sacrifice of the rights and privileges of a majority to the tastes, inclinations, and accepted notions of a few, and clearly, from the latter view, controverted the proper use of the parks as expressed in their charters. The true motive of the barefoots, although reasonably suspected, was not until recently openly manifested. It was simply to use the public parks as advertisements for their so-called new cure. The president of the Brooklyn branch now boldly declares the real wishes of his laudably earnest disciples: "We want a large, free, open space to demonstrate to all the world that the Kneipp treatment is a cure and not merely a diversion for cranks." It must naturally be admitted that it is very much more difficult to prove the former proposition than to com-

bat the latter. If the present frightful death rate of the diseases claimed to be curable by this method can in any way be lowered, why not give these wonder workers an opportunity to be seen and heard? That would appear to be the only way out of the present difficulty of finally settling the now momentous question. The mission becomingly borrows an odor of sanctity from the head and front of its humble and modest projector. Faithful disciples, let your light shine by all means, and when the figurative bushel is thrown away with the shoe may you, while knuckling to this work, continue to glisten with the cleansing invigoration of the morning dew and blend your unconfined exhalations with the grassy scent of breezy lawns.

PRURIGO.

THE question of prurigo was considered of sufficient importance to occupy an entire evening at the recent international congress of dermatologists in London. The discussion, which was participated in by E. Besnier, White, Payne, McCall Anderson, Unna, and various others, is summed up by Sabouraud as follows: Prurigo has no proper lesion. The lesions which are seen are polymorphous. Only one of its symptoms, a functional one, is constant—pruritus. Scratching is the important factor in the objective lesion, which varies according to the tegumentary reaction (urticaria, lichen, etc.) of the individual and the secondary infection. At the base of prurigo there is a nervous lesion, the cause of the itching, the result of chronic intoxication, usually of autointoxication of visceral origin. Sabouraud thinks the discussion decided the triumph of the French doctrine (Besnier, Brocq, Jacquet) over that of Vienna (Hebra).

News of the Week.

A Case of Trichinosis was reported to the health authorities of Paterson, N. J., a few days ago.

The Plague has broken out in Bombay and other parts of the presidency. Over one hundred deaths have been reported as due to this disease.

Dr. James E. Newcomb has been appointed lecturer on physiology at the Teachers' College in this city.

An Epidemic of Whooping-Cough is at present giving trouble to the officers of the Colored Orphan Asylum. There have been about forty cases during the past two weeks.

Diphtheria prevails in Salem, Mass., and several of the schools have been closed in consequence. There are at present about thirty cases known to the health authorities.

Utah State Medical Society.—The second annual meeting of this society will be held in the council chamber, city and county building, at Salt Lake City, Tuesday and Wednesday, October 6th and 7th.

The New York State Medical Association will hold its thirteenth annual meeting at the Mott Memorial Hall in this city on October 13, 14, and 15, 1896.

A Monument to Pasteur is to be erected in Munich. A committee consisting of Professors Pettenkofer, Ziemssen, and Buchner has been organized to solicit subscriptions for this object.

A Chapel for Bellevue Hospital.—Miss Annie Leary has built a chapel in the grounds of Bellevue Hospital for the Roman Catholic patients, as a memorial to her brother, Mr. Arthur Leary. It will be dedicated this fall.

The Bicycle as a Therapeutic Agent.—The wheel has joined the ranks of aperient waters, infant foods, and other indispensable aids to health and long life, if we may judge from an exhibit in a Broadway window. In the window is a bicycle, and below the bicycle is the certificate of an honored member of the profession in a neighboring city, whose reputation as a therapist ought to be very valuable to the manufacturers of the bicycle ridden and approved by him.

Civil Service Examinations.—On Monday, October 5, 1896, the New York City civil service boards will hold a competitive examination at their office (new criminal court building), for the position of house physician at Bellevue Hospital. This position requires a knowledge of the treatment of the insane, and pays a salary of \$1,200 per annum. Applicants must be citizens of the United States and residents of New York State. There will also be an examination for the positions of druggist and assistant druggist, on Tuesday, October 6th, at 10 A.M. The candidates must be residents of the State of New York. Applications should be made to William Briscoe, secretary.

Jenner Centenary in Chili.—Upon the invitation of the Medical Society of Santiago, all the scientific associations of Chili united on May 14th in celebrating the centenary of the discovery of vaccination. An entire number of the *Revista Médica de Chile* is devoted to a report of this celebration, which was held in the hall of the National Conservatory of Music, in Santiago. Orations were delivered by Drs. A. Ossego Luco, R. Dávila Boza, E. Rodríguez Cerda, Lucio Córdova, Adolfo Murillo, and Luis Ugarte Valenzuela, and a poem in honor of Jenner was recited by Dr. Carlos A. Gutiérrez.

A Boon to Canadian Druggists.—An Eclectic Medical School of Milwaukee, with a branch office in Chicago, is sending circulars to pharmacists in Canada, offering them a medical diploma with the degree of M.D. for a small sum. The regular price, the letter says, is \$35.00 and the diplomas are "good, lawful, and valid in Wisconsin, Kansas, Idaho, Wyoming, Michigan, and Indiana," but as they confer no right to practise in Canada the price for them in the Dominion is reduced to \$10.00, C. O. D. We were informed by a Milwaukee correspondent that this disgrace to Wisconsin was to be closed, but it seems that the State still protects the diploma mill.

Frau Klafsky, a prima donna well known in this country, died recently in Hamburg as a result, it is alleged, of a needless trephining operation. She was suffering from severe headache, and a diagnosis was made of tumor of the brain. The skull was trephined, no tumor was found, but the patient died.

Yellow Fever in Cuba shows no sign of abatement, the new recruits constantly arriving in the island from Spain furnishing fresh fuel for the epidemic. The disease is confined almost wholly to the Spanish soldiers, only six of the forty-one deaths in Havana during the past week having occurred among civilians. Of the one hundred and five new cases reported during the same period, eighty-seven were among the newly arrived soldiers.

Impure Water in Chicago.—An Associated Press telegram of recent date reports that the public schools may be closed on the order of Commissioner of Health Kerr, because the water supply afforded them by the board of education, without filters, is impure. A heavy rain carried out to the pipes of the various cribs of the city all of the filth of the sewers, and this has been brought back to the school children in the drinking-water which is furnished them in the school buildings.

St. Luke's Hospital Censured.—A man who was being transferred from St. Luke's to the Harlem, one day last week, died shortly after being placed in the ambulance. At the inquest held by Coroner Dobbs the coroner's physician, Dr. Schultze, testified that in his opinion the man would not have died had it not been for the attempt to transfer him. The coroner's jury brought in a verdict that death was due to alcoholism and delirium tremens, and censured the hospital for negligence.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the United States navy for the week ending September 26, 1896: September 23d.—Passed Assistant Surgeon G. A. Lung detached from the *Vermont* and ordered to the naval hospital, Chelsea, Mass.; Passed Assistant Surgeon H. D. Wilson detached from the Chelsea, Mass., hospital, and ordered to the *Bache*; Passed Assistant Surgeon G. H. Barber ordered to the Naval Academy; Assistant Surgeon M. K. Johnson detached from the *Bache* and ordered to the *New York*; Assistant Surgeon F. C. Cook ordered to the *Vermont*.

Jefferson Medical College.—It is given out that the trustees of Jefferson Medical College have secured additional property, to the extent of twenty by one hundred and forty-eight feet, at the southwest corner of Tenth and Sansom streets, adjacent to the present college building. The plans contemplate the tearing down of the present building and the erection of a handsome structure in its place. Before this is done, however, it is hoped to have the new hospital building at the corner of Tenth and Walnut Streets completed. When this is accomplished, it is possible that the present hospital on Sansom Street will be fitted up for college purposes, to be used while the new college building is in process of construction.

A Case of Leprosy in Montreal.—At a coroner's inquest held recently on the body of a Chinaman who died in Montreal, it was found that death was caused by leprosy.

The Late Sister Irene.—At a special meeting of the New York Foundling Hospital, held September 15, 1896, the following minute was adopted:

"The medical board desires to pay tribute to the memory of Sister M. Irene FitzGibbon, late superior of this institution. Several members of the board have served for more than twenty years, and have witnessed the growth of this work, its transference to larger buildings, and its full development. They recognize the fact that the one person who organized, who procured friends and funds, who planned and built the one great foundling hospital of America was Sister M. Irene. Whatever other forces and agencies were assisting, it has been obvious to all that the central figure, the persuasive, tactful genius, the sweet-souled woman who led to this success was she to whom to-day the medical board pays this parting tribute.

"*Whereas*, The medical board, in the death of Sister M. Irene, the sister superior of the hospital, has lost the first executive officer and a long-trying friend, therefore be it

"*Resolved*, That the board causes to be spread upon the minutes of its records these resolutions of appreciation and sorrow, incorporating the words:

" 'This board has lost the best friend any hospital board ever had.'

"*Resolved*, further, that the sympathy of the board be extended to the reverend mother superior and the sisterhood of the Sisters of Charity; also that a copy of these resolutions be forwarded them and be published in the current medical periodicals.

[Signed]

"J. LEWIS SMITH, M.D.

"J. O'DWYER, M.D.

"GEORGE F. CAREY, M.D.

"*President of the Medical Board.*"

Obituary Notes.—SIR JOHN ERIC ERICHSEN, the well-known English surgeon, died on September 23d, at Folkestone, England, from apoplexy. He was born in 1818, and was educated at University College, London. He was a fellow and ex-president of the Royal College of Surgeons, a fellow of the Royal Society, and of the American Surgical Association, and a member of various other learned and scientific societies. At the time of his death he was emeritus professor of surgery and consulting surgeon to University Hospital. He was surgeon-extraordinary to the Queen.—DR. CHARLES MILNE, of this city, was found dead in his bed, on September 28th, by a servant who went to awaken him. The cause of death was heart disease. He was fifty-six years old, and was a graduate of the University Medical College in 1873.—DR. JOHN C. SACKVILLE was killed at Washington, Pa., on September 23d, by being struck by an express train. He was born in England in 1814, and was educated at Oxford. He served as surgeon with the English army in India, and also with the United States army during the Mexican war.

A Victim of the Faith Cure.—The discriminating coroner of Scranton, Pa., has declined to issue a permit for the burial of a child who died of diphtheria while under the care of local Christian Scientists.

Gloucester County (N. J.) Medical Society.—The fall session of the Gloucester County Medical Society was held at Woodbury, N. J., on September 24th. A number of papers were read and a luncheon was partaken of.

Bogus Diplomas.—A man was recently arrested in Germany for selling university degrees. He had stolen the seals of the University of Berlin and had made and sold at least two hundred and fifty bogus diplomas before he was caught. About one hundred of these diplomas were sold in the Scandinavian countries, fifty in England, and twenty-three in Germany.

Against Vivisection.—At a meeting of the American Humane Association held at Cleveland on September 24th, a resolution was unanimously passed recommending the general adoption throughout the United States of laws regulating the practice of vivisection. The members were urged to use their personal efforts to secure the enactment of the necessary legislation in the different States.

Canadian Medical Association.—At the recent meeting of this association the following officers were elected: *President*, Dr. V. H. Moore, Brockville, Ont.; *Vice-Presidents*, Dr. Peter Conroy, Charlottetown; J. F. Black, Halifax; Thomas Walker, St. John; J. M. Beausoleil, Montreal; W. W. Dickson, Pembroke; R. S. Thornton, Deloraine; E. H. C. Rouleau, Calgary; E. B. C. Hannington, Victoria; *General Secretary*, Dr. F. N. G. Starr, Toronto; *Treasurer*, Dr. H. B. Small, Ottawa. The next meeting in 1897 will be held in Montreal, in conjunction with the meeting of the British Medical Association.

Vital Statistics of Philadelphia.—For the week ending September 19th, there occurred in the city of Philadelphia 427 deaths; 42 more than during the preceding week and 61 more than during the corresponding period of the previous year. Of the whole number 158 occurred in children under five years of age. The principal causes of death were as follows: Pneumonia, 37; pulmonary tuberculosis, 36; cholera infantum, 26; diseases of the heart, 22; carcinoma, and inflammation of the brain and membranes, each 19; apoplexy, 17; diphtheria, 16, marasmus, 14; nephritis, 13; old age, 12; typhoid fever, 10. There were reported during the week 57 cases of typhoid fever, 46 of diphtheria, and 10 of scarlet fever.

A Munificent Bequest.—By the will of the late Enoch Pratt, a banker and philanthropist of Baltimore, a sum of money estimated to be upward of two million dollars is bequeathed to the Sheppard Asylum, with the stipulation that the name of the corporation be changed to the Sheppard and Enoch Pratt Hospital. It is intended that the income derived from the fund shall be used to complete the present buildings and grounds and then to erect an additional

building with a capacity of two hundred beds. After this has been done the fund is to be devoted to the care of the indigent insane "free of cost, by the most approved methods known to medical science."

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, held on September 23d, Dr. E. E. Montgomery read a paper on the "Treatment of Retrodisplacements of the Uterus." He contended that the displacement itself is generally not of so much significance as the accompanying complication, and that no procedure which does not take cognizance of the latter condition will prove a satisfactory method of treatment. The following recommendations were made: In recent cases, when the uterus is freely movable, the use of a medicated tampon or of a pessary. In recent cases, when a plastic exudate is present, together with adhesions, and suppurative salpingitis can be excluded, the employment of massage, supplemented by the medicated tampon, and restoration of the mobility of the uterus, followed by the introduction of a pessary. In chronic cases, when the uterus is movable, the practice of curettage followed by suture of the round ligaments in front of the uterus through anterior colporrhaphy. When ovarian or tubal disease exists as a complication, the practice of curettage, followed by abdominal incision, treatment of the diseased appendage, and fixation of the uterus to the abdominal wall. If adhesions are present, without serious tubal or ovarian disease, the practice of curettage in conjunction with shortening of the utero-sacral ligaments, after separation of the adhesions, through the posterior vaginal incision. Dr. John M. Fisher exhibited a specimen of multiple fibroids of the uterus, in the removal of which a cyst situated in the broad ligament caused some doubt as to whether it was the bladder.

Pathological Society of Philadelphia.—At a stated meeting of the Pathological Society of Philadelphia, on September 24th, the following presentations were made: Dr. J. A. Scott, "Carcinoma of the Pancreas, with Secondary Growth in the Liver;" Dr. D. Riesman, "Atheroma of the Vessels in a Case of Diabetes Mellitus in a Girl Thirteen Years Old;" Dr. A. A. Eshner, "Multiple Aneurisms of the Aorta, with General and Extensive Atheroma of the Entire Vascular System, Death Resulting from Rupture into the Abdominal Cavity; Typhoid Ulceration, Involving both Large and Small Intestine, from a Case Terminating Fatally during a Relapse;" Dr. A. E. Taylor, "Malarial Hæmatozoa; Thrombosis of the Pulmonary Artery in a Child;" Dr. T. S. Westcott, "Urethral Calculi from a Case Terminating Fatally as a Result of Cerebral Hemorrhage;" Dr. F. A. Packard, "Tuberculous Laryngitis, with Abscess on the Trachea, and Slight Involvement of the Lungs;" Dr. C. J. Garitee, "Heart and Kidneys from a Case of Verrucose Endocarditis and Parenchymatous Nephritis;" Dr. J. D. Steele, "Contracted Gall Bladder, with Gall Stones;" Dr. Joseph Sailer, "Perforated Aortic Leaflet from a Case of General Septicæmia;" Dr. A. Hand, "Meningocele, with Congenital Absence of One Kidney and Ureter."

Reviews and Notices.

MEDICAL AND SURGICAL REPORT OF THE PRESBYTERIAN HOSPITAL IN THE CITY OF NEW YORK. Volume I., January, 1896. Edited by ANDREW J. MCCOSH, M.D., and WALTER B. JAMES, M.D.

BESIDES the usual statistical report, there are records of clinical histories by the various members of the staff, and a chapter on the preparation of dressings, sutures, sponges, etc., compiled by Miss E. S. Anthony.

THE MULTUM IN PARVO REFERENCE AND DOSE BOOK. By C. HENRI LEONARD, M.A., M.D., Professor of the Medical and Surgical Diseases of Women, Detroit College of Medicine. Detroit: The Illustrated Medical Journal Company. 1896.

THIS is a new edition of Leonard's dose book, printed on thin paper and bound in flexible leather with round corners, making it easy to be carried in the pocket. The book not only gives the doses of all drugs used in rational medicine, but also contains numerous tables of solubilities, poisons and their antidotes, urinary tests, incompatibilities of drugs, etc.

THE AMERICAN ACADEMY OF RAILWAY SURGEONS. Report of the Second Annual Meeting, Held at Chicago, Ill., September 25, 26, and 27, 1895. Edited by R. HARVEY REED, M.D., Columbus, O. Chicago: American Medical Association Press. 1896.

THIS edition of the transactions of the American Academy of Railway Surgeons is a neat little volume of over two hundred pages, well printed and well edited. The papers vary considerably in merit, but all of them bear witness to the interest of the writers in their work, an interest which augurs well for the future of this important branch of surgical employment.

A SHORT COURSE OF EXPERIMENTS IN GENERAL CHEMISTRY, WITH NOTES ON QUALITATIVE ANALYSIS. By CHARLES R. SANGER, A.M., Ph.D., Eliot Professor of Chemistry in Washington University. St. Louis: Published by the Author. 1896.

THE author has endeavored to present in this course a series of experiments teaching practically as well as theoretically as much chemistry as it is possible to teach in the limited time which can be devoted to it in one year at a medical school. No attempt is made to teach the subject from a purely medical standpoint, for, as the author very wisely says, a good theoretical and practical foundation is necessary before taking up the special subject of medical chemistry.

ATLAS OF THE DISEASES OF THE SKIN. By H. RADCLIFFE CROCKER, M.D., F.R.C.P., Physician to the Department for Diseases of the Skin, University College Hospital; formerly Physician to the East London Hospital for Children; Examiner in Medicine at Apothecaries' Hall, London. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

FASCICULUS XVI. of this series of illustrations from original drawings, with descriptive letterpress, has just come to hand, completing the work, whose many excellent features have from time to time been referred to in these columns. The first plate, representing impetigo contagiosa gyrata, strikes one at first as being overdrawn in the definition of erythematous outline of the areola. That the situation of lesions upon the back, as here portrayed, is unusual goes without saying, but, as it is well known that the affection may extend over the entire body, even to parts which cannot be easily reached by the hands, the diagnosis need not be questioned on that account.

Excellent plates of mycosis fungoides and pemphigus are presented, and those portraying the various nail and tongue affections are most instructive.

Acanthosis nigricans, myxœdema, and one-sided lentigo are among the rarer affections reproduced. On the whole, this last fasciculus is in a way the crowning number of the series.

Dr. Crocker deserves the highest commendation for presenting so excellent a work, and the publishers should be complimented upon the manner in which they have brought it out.

MANUAL OF MIDWIFE'RY. For the Use of Students and Practitioners. By W. E. FOTHERGILL, M.A., B.Sc., M.B., C.M., Buchanan Scholar in Midwifery, University of Edinburgh; Late House Physician to the Simpson Memorial and Royal Maternity Hospitals, and Gynecological Wards, Royal Infirmary, Edinburgh; Neil Arnott Prize-man in Physiological Physics; Scottish Universities Extension Lecturer; Honorary Surgeon to the Chorlton-on-Medlock Dispensary, Manchester. New York: The Macmillan Company. 1896.

THIS is a very concise yet complete guide for the student and young practitioner. It is of convenient size, well printed, and well illustrated. While it claims to be "a book for Edinburgh men by an Edinburgh man," we can see no reason why its teachings could not be profitably followed by students elsewhere, since the science of which it treats is universal in its application. The author follows the usual plan of beginning with the anatomy and physiology of the female reproductive organs, then taking up pregnancy, normal and pathological; labor, normal and abnormal; obstetrical operations; the puerperium; and closing with a brief chapter on the hygiene of infancy. The author's style is easy and comprehensible, so that the reader has only to occupy himself with the subject matter and is not distracted, as in so many works by medical writers, by efforts to interpret the English. The affectation of the printer in employing two letters in place of a diphthong is not to be commended.

PRACTICAL POINTS IN NURSING: For Nurses in Private Practice, with an Appendix Containing Rules for Feeding the Sick; Recipes for Invalid Foods and Beverages; Weights and Measures; Dose List; and a Full Glossary of Medical Terms and Nursing Treatment. By EMILY A. M. STONEY, Graduate of the Training School for Nurses, Lawrence, Mass.; Superintendent of Training School for Nurses, Carney Hospital, South Boston, Mass. Illustrated with 73 Engravings in the Text and 9 Colored and Half-tone Plates. Philadelphia: W. B. Saunders. 1896.

THE title of this book indicates clearly the nature of its contents. It is intended to serve as a guide to the nurse in her private work. The writer expresses herself clearly and intelligibly, and the descriptions are supplemented by numerous instructive illustrations.

SYSTEM OF SURGERY. Edited by FREDERIC S. DENNIS, M.D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College; Visiting Surgeon to the Bellevue and St. Vincent Hospitals; Consulting Surgeon to the Harlem Hospital and Montefiore Home, etc. Assisted by JOHN S. BILLINGS, M.D., LL.D., D.C.L., Deputy Surgeon-General, U. S. A. Volume IV. New York and Philadelphia: Lea Brothers & Co. 1896.

THIS final volume of Dr. Dennis' excellent work is fully equal in interest of subject matter, authority of the writers, and beauty of illustrations and typography to any of those which have preceded it. The first article is on "Tumors," by the editor, and following this come "Hernia," by W. T. Bull and W. B. Coley; "Surgery of the Alimentary Canal from the Pharynx to the Ileo-cæcal Valve," by M. H. Richardson and Farrar Cobb; "Appendicitis," by Frank Hartley; "Surgical Treatment of Appendicitis," by Charles McBurney; "Surgery of the Alimentary Canal from the Ileo-cæcal Valve to the Anus," by Lewis S. Pilcher; "Surgery of the Liver and Biliary Passages," by Robert Abbe; "Surgical Disorders and Diseases of the Uterus," by William M. Polk; "Surgical Diseases of the Ovaries and Tubes," by Joseph Taber Johnson; "Minor Gynecological Surgery," by Henry C. Coe; "Symphyseotomy," by William T. Lusk; "Surgery of the Thyroid Gland," by Robert F. Weir; "Surgical Peculiarities of the Negro," by Rudolph Matas; "Diseases of the Female Breast," by Frederic S. Dennis; and "The Use of the Roentgen Rays in Surgery," by W. W. Keen. The volume is concluded by an index to the present volume and a general index to the entire work. The latter has been most carelessly made and is absurdly incomplete, with the result that what would otherwise have been a valuable work of reference is rendered utterly useless as such. As a text-book, to be read and studied by the student and young practitioner whose time is unlimited, the work can be commended.

THE MEDICAL AND SURGICAL USES OF ELECTRICITY.

By A. D. ROCKWELL, A.M., M.D. Illustrated with 200 engravings. New Edition. New York: William Wood and Company. 1896.

FOR twenty years and more the work of Beard and Rockwell has been the leading authority in this country on the subject which it treats. They were the pioneers in the field of electro-therapeutics, and enunciated ideas and methods which have stood the test of time. The present work by Dr. Rockwell is the offspring of the former, and, as he states in the preface, has been thoroughly revised and mostly rewritten, the old stereotyped plates having all been destroyed. The illustrations have been newly drawn and many new ones added, so that the author again offers to the profession a treatise in every way complete and modernized. Electricity in medicine has assumed proportions and an importance which cannot be ignored. When the author of this treatise and his associate, the late Dr. Beard, first began their investigations, the subject of electro-therapeutics was little known. For years it gained ground slowly, but within the last decade it has felt somewhat the great strides made by electricity in its commercial aspect. Instruments of precision and greatly improved apparatus have rapidly developed. Schools of instruction have been established, and he who is still ignorant of the possibilities of electricity in medicine and ignores its claims has failed as a physician to keep abreast the current of the times. The influence of electrization over nutrition, the central idea of the work, and which the authors were the first to enunciate and develop, has received wide recognition and is indeed the basis of its medical use. The chapter on Ohm's law alone will well repay the reader. It is the basis of all electrical measurement, indispensable to the worker in electricity, and so clearly discussed and illustrated as to make this abstruse but most important subject plain to the dullest comprehension.

Among the chapters new or entirely rewritten are those devoted to the Roentgen rays in diagnosis and to static electricity, in which the aid of Dr. S. H. Monell, of Brooklyn, is acknowledged. The work plainly sets forth all the fundamental principles of electricity in its relation to disease, is clear in detail, and cannot fail to aid greatly all who are interested in this department of medical science.

A SYSTEM OF MEDICINE. By Many Writers. Edited by THOMAS CLIFFORD ALBUTT, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, etc. Volume I. New York: The Macmillan Company. 1896.

THE first article in this volume, after the editor's introduction, is by Dr. John S. Billings, and two other articles, namely, "Massage," by Dr. J. K. Mitchell, of Philadelphia, and the bacteriological section of "Relapsing Fever," by Dr. Westbrook, of Minneapolis, are from the pens of Americans. The other contributors are British, some of them well known by their writings to the profession in this country, others with a local reputation doubtless, but whose names are not yet familiar in America. The first half of the volume is taken up with a number of short essays on miscellaneous subjects, entitled "Prolegomena." Among these one on the "Medical Geography of Great Britain" is of local interest only, and another on "Nursing" seems as out of place in a work of this sort as would be a collection of cooking-recipes or a chapter on the compounding of prescriptions. The article, which is by Miss Hughes, of Bolton, is an excellent one, however, and if it could be detached from the rest of the volume and somewhat amplified would serve as an excellent book to put in the hands of an amateur called upon to nurse a serious illness. The best of these "Prolegomena," at least those which have interested us the most, are "Inflammation," by Adami; "Fever," by Burdon-Sanderson; "The Laws of Inheritance in Disease," by Hutchinson; and "Principles of Drug Therapeutics," by Leech. The second division of the volume is devoted to a consideration of fevers. The principle of subdivision of labor has been carried here to a rather extreme degree, several of the articles having been divided among two or more writers, and one, that on "Cholera Asiatica," being the product of the combined labors of no less than five authors, two of whom treat of the etiology, two more of the bacteriology, and one of the symptoms, pathology, and treatment. This is a refinement of specialism that might, we think, have been avoided with advantage. As a whole, however, the work is one that can but com-

mend itself as a faithful exponent of British medicine, and one that gives promise of deserving a success equal to that of "Reynolds' System of Medicine," of which it will now doubtless take the place.

A VEST-POCKET MEDICAL DICTIONARY. Embracing those Terms and Abbreviations which are Commonly Found in the Medical Literature of the Day, but Excluding the Names of Drugs and of Many Special Anatomical Terms. By ALBERT H. BUCK, M.D. New York: William Wood and Company. 1896.

NOTWITHSTANDING the appearance of a new medical dictionary every year or two for the past decade, there has been up to the present none in existence which met the needs of the physician and especially the student. Of lexicons in one or several large volumes there is an ample choice, but they can be consulted only in the library, and even then the labor of taking a heavy book from the shelf, and the interruption to reading caused thereby, are often enough to deter one from looking up a half-understood word. Furthermore many busy practitioners have little time for quiet study in the library, but must read their books and journals while riding to their patients, and to such persons a ponderous lexicon reposing on the bookshelf is no more useful than if it were printed in Chinese characters. But it is the student in the classroom who especially feels the need of a dictionary which he can have always with him, and to which he can turn whenever an unfamiliar word strikes his ear. To these, the busy practitioner and the student, this little book will come as a welcome friend. It is really of vest-pocket size, being but two and a half inches wide by three and a half long, and about one-half inch in thickness, yet it contains the definition and pronunciation of over five thousand words. We are aware that there are other professedly pocket dictionaries which contain a much greater number of words, one indeed which bases its claim to the preferences of purchasers on the stated number of words it contains. Of course, the value of such a work, which does not pretend to contain all the terms known to medicine, must depend entirely upon the intelligent judgment of the author as to what words shall be admitted and what excluded. A careful examination of the lexicon has caused us to admire the rare discrimination shown by Dr. Buck in this task. Obsolete terms and the creations of some ambitious word coiner, which would never be encountered in a lifetime of study of contemporaneous literature, have been rigidly excluded, but of the new terms and the old ones still current we have failed to find scarcely one in a most thorough search. In this careful discrimination and selection the book possesses great advantages over similar works which base their claims upon the large number of words they contain. There is quality in Dr. Buck's book rather than quantity. Although the book contains such a large number of words in such small compass, the type is of good size and can be read with ease without the least strain of the eyes. It is substantially bound in flexible leather covers.

Oxygen in the Treatment of Suppurating Surfaces.—Dr. W. Peyre Porcher writes in the *North Carolina Medical Journal* concerning the use of oxygen in the treatment of old wounds and suppurating surfaces of all kinds, as practised by Dr. Stoker. He says that he saw old sores of thirty years' duration, ulcers extending from knee to heel, a burn 10 x 8 inches on the back, all in rapid progress of healing simply by continued exposure to oxygen gas, pure or diluted; ear polyps dried up and dropped off and atrophic rhinitis was materially improved. There were no hard indurations in the cicatrices of these old ulcers, but the surface was smooth and apparently full of blood-vessels. Cultures from the wounds were regularly taken and the progress toward healing noted. At the recent meeting of the British Laryngological Association, cases of atrophic rhinitis and purulent middle-ear disease were shown which had greatly improved under the application of oxygen. Mr. Lennox Browne and several members reported cases in which the treatment had been used with success.

Society Reports.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Twentieth Annual Meeting, Held at the Hot Springs of Virginia, September 8, 9, and 10, 1896.

THE attendance was small, chiefly owing to the fact that many members were absent in Europe, where they had been attracted by the International Dermatological Congress.

President's Address.—DR. A. R. ROBINSON, of New York, delivered an address of welcome, in which he first spoke in glowing terms of the character and ability of the only active member the association has ever lost by death, Dr. Edward Wigglesworth, of Boston. The field which the dermatologist cultivates the speaker looked upon as a most important and extensive one, and still the specialist in this branch does not yet hold the position he should in the eyes of the general profession. One reason of this is the attitude of most medical schools in this country in not looking upon the study of cutaneous diseases as a natural and necessary part of the college curriculum. Medical education, he said, has not yet reached a common-sense basis. The school has no right to pronounce a man capable of treating diseases of which it has given him no knowledge. Classes are habitually too large for proper clinical instruction. The physician graduated without the ability to diagnose and properly treat diseases of the skin is not justified in accepting a fee from a patient with a disease of this nature, if a properly qualified physician is within reach. The English custom of granting one degree for graduates in medicine and another for graduates in surgery, if adopted here would, the speaker held, be a step in the right direction. Attention was called to the many unnecessary operations which result from the family physician calling in a surgeon instead of a dermatologist in doubtful cases, in which the diagnosis lies between sarcoma, lupus, tuberculosis, and syphilis. Instances were quoted to show how slight and often overlooked eruptions pointed to the true condition, and would, if recognized, save the patient from the knife. To obtain proper recognition by the schools, the general practitioners, and hospital authorities, so that teaching and practising in public as well as private may become what it should be, the dermatologist ought to be more aggressive toward notorious offenders, and show by his works the great importance of this special branch to humanity. Papers representing original research should be published only in journals devoted to the special branch, so that the dermatologist could keep track of the subjects; while those intended to instruct the general practitioner or to acquaint him with the fact that the writer is devoting his time to dermatology, can be printed in journals devoted to general medicine. The speaker opposed strongly the reading or publication of papers, the sole purpose of which was to advertise the writer. Admission to the association should be a goal for every true worker in dermatology, to be gained by hard labor. One who writes for notoriety is not likely to bring much credit upon the association, one of whose objects is to guard the dignity of dermatology.

Paget's Disease of the Nipple.—DR. G. T. JACKSON, of New York, read a paper upon this subject, and described a case occurring in a woman, aged fifty-two years. After a dermatitis about the nipple, a tumor developed within the substance of the breast, which Dr. Curtis amputated with good results; but subsequently a similar tumor formed in the opposite gland. Dr. Ely, who made the microscopical exami-

nation, reported that the growth was not cancerous. Dr. Jackson advocated early amputation in Paget's disease as soon as possible after a positive diagnosis had been made, since cancer is so prone to develop.

DR. FORDYCE thought the pathologist's report indicated that a fibrous growth was present in the gland before the eczema-like disease occurred about the nipple, while text-books teach that the disease always begins in the epidermic cells and extends secondarily along the galactiferous ducts.

DR. BOWEN agreed with this criticism.

DR. DUHRING said at first there was an inflammation of the skin about the nipple, clinically identical with eczema. Five years later an entirely different clinical picture was presented. Epithelioma masked the eczema. He had suggested the name "eczematoid epithelioma," since the vast majority of cases became cancerous.

DR. WHITE thought the case described could not be regarded strictly as one of Paget's disease. If improvement does not take place in the latter disease from ordinary remedies, it is proper to advise excision.

DR. ROBINSON said he failed to see that any connection had been shown between the affection of the breast and the nipple changes. There might have been fibroma in accidental combination with dermatitis. He had seen cases diagnosed as Paget's disease, in which without operation recovery took place.

DR. JACKSON said, in closing, that the clinical appearances had been typical, and he thought any one present would have made this diagnosis.

A Pathological and Clinical Classification of the Diseases of the Skin.—DR. L. A. DUHRING, of Philadelphia, read a paper with this title. He presented a table, showing the diseases arranged and grouped according to the views advanced. Nine classes were given: 1, Anæmias; 2, congestions; 3, inflammations; 4, hemorrhages; 5, neuroses; 6, hypertrophies; 7, atrophies; 8, new growths; 9, diseases of the appendages of the skin. The last class was divided into diseases of the (a) sweat glands; (b) sebaceous glands; (c) the hair and follicles; (d) the nails. The structures composing the appendages of the skin, especially the follicles, hair, and nails, were subject to such varied forms of disease that it was eminently proper and useful to lump them together. The classification was based on the pathology, histopathology, and anatomy of the skin, note being also taken of the chief primary lesions of disease, as well as of the other prominent clinical features, with a view to aiding the clinician in recognizing the various diseases of the skin.

DR. WHITE did not think it an improvement on Dr. Duhring's previous classification. He found many affections placed under one head which might as well be placed elsewhere, and the last class appeared to be an "*omnium gatherum*." In the present state of knowledge, the etiological element can scarcely be ignored. It seemed to him more important than the anatomical. Pityriasis rubra and dermatitis exfoliativa, he said, were considered as separate affections.

Various criticisms were afterward made.

DR. MORROW said an etiological classification was the ideal one, and it seemed a step backward to entirely ignore the etiological element. Finding the various tinea in different classes would tend to confuse the students. Morphœa and sclerodermœa, classed as atrophies, he thought, were recognized by all to be primarily hypertrophies.

DR. ALLEN said a satisfactory classification seemed an almost impossible task, and still he thought it a reproach that the association had to rely upon an alphabetical list. He thought Dr. Duhring had attempted a necessary work, and hoped he would persist in his effort to improve it.

DR. ROBINSON thought the classification would not be as useful to the reader or the teacher as Dr. Duhring's original one. It was quite complicated. An etiological classification was at the present time impossible, and probably always would be, because many agents are capable of presenting widely differing pathological processes. The general arrangement seemed correct, showing much serious study, but still presented many objectionable features.

DR. DUHRING, in closing, said that he had given much thought to the matter, and during the past twenty-five years had laid out a half-dozen classifications on different lines. While a few diseases behave well under an etiological classification, the larger number cannot be so classified. It becomes too confusing for the student. The class of diseases of the appendages of the skin have been introduced to give a place for the convenient grouping of a number of diseases. In forming a classification it is not well to depart too far from old lines. The speaker felt sure that he could show a form of pityriasis rubra which would not be considered the same as dermatitis exfoliativa.

A Peculiar Affection of the Mucous Membrane of the Lips and Mouth.—DR. J. A. FORDYCE, of New York, read a paper entitled as above, in which he reported a case of a peculiar mottling of the lips and mucous surface of the cheeks, more noticeable when the parts were put upon the stretch. The condition had existed for two years without subjective symptoms, but the patches had gradually increased in area. The microscope showed a degeneration of the protoplasm of the epithelial cells. The muciparous glands were not involved. The specimen and colored drawings were shown.

DR. MORROW said it was an interesting point that the same condition had been found in several members of the patient's family. The nature could be determined only by the microscope.

DR. WHITE had seen superficial changes suggestive of the case reported.

DR. BOWEN thought there might be a plugging of the glands by the process described, which would account for the yellowish or whitish bodies seen beneath the surface. He had seen bullæ followed by atrophy and attended with the formation of bodies similar to those by plugging up of glandular structures.

DR. ALLEN thought the condition a very common one, but the cases he had observed had not sought treatment. At times it constitutes almost a deformity.

A Favus-Like Eruption of the Oral Mucous Membrane Caused by Aspergillus Nigrescens.—

DR. WINFIELD, of Brooklyn, gave the history of a case which had been referred to him by Dr. Browning, who had had it under observation for some weeks. A small ulcer had first appeared on the middle line of the roof of the mouth, about half way between the incisors and the soft palate. It was supposed at first to be an ordinary canker sore, giving discomfort only when bread-crusts or other hard substances pressed against it. The patch increased slowly in size, and others formed in the neighborhood. Two weeks after its first appearance the patient consulted Dr. Browning, and, as the patch continued to enlarge, a course of antisyphilitics was given, but without good effect. It was then suspected that the inflammation was due to a local parasite, and bichloride and other parasitocides were employed, without avail. A drawing was shown, revealing a lumpy patch extending from just behind the incisors to within one-fourth of an inch of the soft palate. Cup-shaped elevations on the soft palate appeared on either side of the middle line. A firmly attached membrane, giving rise to hemorrhage when forcibly removed, covered the areas. The color of the recent deposit suggested the sulphur-colored scutula of

favus; where it had remained undisturbed it was darker. A few minute ulcers were scattered over the larger patch. With low power the growth was recognized under the microscope as a fungus differing from the achorion. The mycelium network was composed of delicate fibres, bearing perpendicular fructifying hyphæ. Scattered over the field were a number of fruit receptacles and a few spores. The manner of fructifying showed that the fungus did not belong to the oidium, but to the ascomycetous genus. Cultures showed it to be *aspergillus nigrescens* which had caused the inflammation. Upon applying twenty-five-per-cent. ethereal solution of "pyrozone," improvement was immediately noticed. The pseudo-membrane disappeared and new patches ceased forming. After seven weeks' treatment the patient was well. Literature has failed to show a similar case, although many instances were recorded in which *aspergillus* has been found in the human ear. The spores were supposed to have been implanted in the mouth through the medium of cheese, strong and mouldy varieties of which the patient was very fond of eating.

What Effect do Diet and Alcohol Have upon the Causation and Course of the Eczematous Affections and Psoriasis?—

DR. J. C. WHITE, of Boston, opened the discussion on this subject. He said that little new in this line had been brought out at the recent congress in London, the president of which had expressed his continued belief that leprosy was due to a certain article of diet. Some recent discussions have shown that observations of the past have been so inexact that no trustworthy conclusions can be drawn from them. The importance of the bearing of diet upon eczema has been shown to be greatly overestimated. It has also been denied that the existence of eczema proves the coexistence of gout. Improper selection of food, its improper preparation, and the use of food containing toxic properties are all harmful. In certain nomadic tribes the diet is largely animal; among certain religious sects it is almost exclusively vegetable; while it is only recently that certain inland people have had fish as a common article of diet. In spite of these opportunities, the therapeutic test has rarely been applied on an extensive scale. Articles of food which increase the cutaneous circulation or excite the nervous system, and so exaggerate a pruritus, certainly have a bearing upon eczema. The diet in this disease should be the same as in all other inflammatory processes. As he does not recognize any connection between eczema and any so-called diathesis, he would deny the efficacy of systems of diet based upon the existence of such diathesis. He recognized both a direct and an indirect influence on the maintenance of the disease by alcohol, but did not regard it as an important factor in its causation. Personally he believed that diet and alcohol had no influence on the causation and course of psoriasis in general, but in exceptional types they have a temporary importance. The successful treatment of these two diseases is still a matter of empirical experimentation.

DR. FORDYCE said eczema was a general term, including many different conditions. Our etiological knowledge is so meagre that it is difficult to express definite views upon the influence of diet and alcohol on these affections. A study of the natural history of psoriasis would, perhaps, explain the divergent views regarding this supposed influence. In the early progressing stage the development of psoriasis may be influenced by alcohol and, perhaps, by diet. In the stage of decline the disease can be influenced by almost any drug or any food.

DR. JACKSON believed alcohol aggravated eczema and psoriasis. Perhaps we shall soon have to allow the influence of micro-organisms in eczema. The more simple the diet the sooner the cure. He had

seen cases treated by Dr. Fox with all kinds of exclusive diets, and had been unable to observe any decided effect from any of them. Simplicity is of prime importance.

DR. DUHRING said that in so broad a subject only certain points could be touched upon. We must distinguish between food as a cause and food as an injurious factor in disease. He would seriously question food being the cause of eczema, but it may possess a direct injurious influence. In many cases it decidedly aggravates an eczema already existing. As to alcohol, he did not believe it exerted much influence in causation, but all would admit that it was injurious. It was far from being such a potent factor as is food.

DR. DYER said he had repeatedly watched cases of recurrent infantile eczema, notably that attacking the face. Whenever he investigated the dietary he usually found it faulty. Without internal medication and with indifferent applications, a cure was usually effected by regulating the food.

DR. MORROW said that in Honolulu these two diseases were the ones habitually seen, and the diet was almost exclusively vegetable. A certain proportion of subjects of infantile eczema suffer from malassimilation. Some of the elder children are allowed coffee, vegetables, meat, and a piece of bacon to suck. By correcting these faulty conditions, an eczema will show marked improvement. In dispensary practice he gave no instructions as to diet, knowing that they would not be observed. Private patients did better, mainly for this reason. Alcohol injured in eczema, just as it does in syphilis, because of the influence on the circulation. We must recognize the influence of alcohol in favoring relapses in psoriasis.

DR. ALLEN said his hospital experience accorded with that of Dr. Morrow, in that relapses occurred promptly and in a severe form in those who drank spirits as soon as they were discharged. Children with eczema of the face were generally found to have some error of diet, and the disease seemed aggravated by it.

DR. ROBINSON said if one lived upon mutton for a number of weeks the molecular constitution would differ from that after an equal period on a mixed diet. This point was brought forward by Huxley twenty or thirty years ago. The diseases of children are of two classes, toxic and parasitic. There is no direct toxic agent, but the ground is made favorable for the development of such organisms as reach the surface directly. In fermentative forms of indigestion toxins are formed, and in this way a toxic eczema may become established. He especially condemned sweets, and particularly the cheap candies these subjects are often found to consume. Correction of the intestinal disturbance alone almost invariably leads to a disappearance of eczematous eruptions, but more slowly than if local applications are also made, especially if they are such as are unfavorable to the development of parasitic organisms. Urate of sodium has been found upon the skin surface in gout, and he could recall an instance in which internal treatment directed against the gouty condition promptly removed an eczema, which other treatment had failed to influence. In psoriasis he thought food had little influence. He depended upon establishing an alkaline state of the system; as long as the urine remains acid, he is unable to successfully treat such cases. If the diet is properly regulated, less alkaline medication is required.

DR. WHITE, in closing, said we had not as yet any positive knowledge that eczema was a specific parasitic disease. At present that claim was a mere theory. It must not be forgotten that eczema was most frequent in the early months of infancy, while the food was of the simplest nature. Up to the tenth year the complexity of the food was constantly increasing, and still ecze-

mas became less frequent. He would be inclined to draw more serious conclusions from Dr. Dyer's remarks if regulation of diet had been followed by the results without any local treatment.

DR. DUHRING said that food influences the nutrition of the skin in eczema in a notable degree, and hence must be regarded as an important factor in the history of eczema.

Symmetrical Morphœa.—DR. P. A. MORROW, of New York, reported a case of symmetrical morphœa attended with formation of bullæ and ulceration. The striking features of the case were the number and size of the plaques, their symmetrical distribution, the occurrence of bullæ, and the extensive breaking down and ulceration of the affected tissues.

He was consulted in regard to it first by Dr. A. H. Crane, of Waterbury, Conn., who had been called in on the suspicion that it was a case of leprosy, and subsequently Dr. Rodger had brought the patient to his office. He was a man sixty-five years old, whose health had been good with the exception of attacks of rheumatism. One year ago he began to experience stiffness in the right thigh and observed that the skin in this region was changed in color, and felt stiff, hard, and unyielding. Soon after this white patches appeared on the left thigh and later below both knees. In January last similar patches appeared on the lower portion of the abdomen, about the hips, sides of the trunk, and on the back between the shoulders. The patches below the knees became painful and ulcerated, and did not heal for six months. In May (1896) the upper and middle region of the right thigh was occupied by a large irregular plaque covering almost the entire anterior and outer surfaces. It was made up of smaller plaques which had become confluent, their lines of coalescence being distinguishable. Over the opposite thigh the plaques are symmetrically disposed, but not confluent. Band-like patches are seen above Poupert's ligament, extending upward and outward on either side. On the lateral and posterior aspects of the trunk are symmetrical patches; on the right leg the ulcerative process has extended into and above the popliteal space. The patches are round, oval, or of irregular contour. The color is lardaceous white, the older ones having a yellowish or parchment coloration. Each patch is surrounded by a clearly defined lilac border. The skin over the patch cannot be pinched up, there is complete absence of hair, and the secretions are entirely suppressed over the affected areas. There is lancinating pricking pain in the ulcerated surfaces, and a hypersensitiveness to cold is complained of. In August there was marked improvement, the ulcerations being healed. Here and there over the cicatrix small excoriations and ulcerations formed from time to time, due to the rupture of bullæ the size of large peas, of a gray color, giving exit to an amber-colored fluid. The occurrence of bullæ has been a constant feature for two months.

Treatment consisted in giving thyroid extract tablets, fifteen to twenty-five grains daily, along with large doses of iodide of potassium, forty to forty-five grains t. i. d.—replaced after the second visit by salicylate of sodium and Merck's thyroïdin in the same dose as the extract. There has been progressive improvement. Many patches are in process of involution. The skin is softer, more supple, and the patient seems in a fair way to recover.

Mycosis Fungoides and Sarcomatosis Cutis.—DR. J. T. BOWEN, of Boston, read a paper on this subject. There is often very great difficulty in differentiating these two types of disease. The reader possessed a series of photographs illustrating this point. A study of his cases and of others which had been reported would make it probable that there are transitional forms between the two affections, as has been

suggested by Kaposi. A histological study of the papules, which resemble the prurigo of Hebra showed a structure exactly corresponding with the true prurigo papule.

DR. WHITE asked how large these nodules were, and whether the speaker referred to large papules or the secondary large nodules occasionally developed in prurigo.

DR. BOWEN said that he referred to the true prurigo papules.

DR. WHITE thought we must regard the fugitive character of these lesions as common to both mycosis and sarcoma. There was a great difference in the maximum size of lesions in the two affections, but it was only a matter of degree. A nodule the size of a pigeon's egg would disappear rapidly in one case, and one the size of a goose egg would disappear rapidly in true mycosis fungoides. How far this indicated any common nature he was unable to say.

DR. DUHRING preferred the term granuloma fungoides. The diagnosis was simple in most instances when the disease had become fully developed. It was quite different from sarcoma. There was much confusion in the histological condition, and he was not prepared to distinguish clearly between the two. The inflammatory element was more marked in granuloma fungoides.

DR. FORDYCE said there was nothing very distinctive in the pathological anatomy of mycosis fungoides and certain forms of sarcomatosis. Certain forms of spindle-cell sarcoma could be differentiated with the microscope.

DR. ROBINSON did not think that the disappearance of the tumors should exclude the term sarcoma, which really meant only a new growth in the proper sense of the term. He had seen epitheliomatous tumors disappear without treatment, proving that they were not simple new growths. He did not think that certain cases of mycosis fungoides could be differentiated from multiple sarcoma, certainly not by pathological findings alone.

DR. BOWEN, in closing, said the term granuloma fungoides was objectionable, because it had not been shown to be an infectious granuloma. The term mycosis fungoides seemed the least objectionable.

Xanthoma Diabeticorum was the title of a paper next read by DR. ROBINSON, of New York, in the course of which he described the case of a woman, who had never been jaundiced herself and had never had a relative thus affected. During the past ten years, however, she had suffered from gall stones. The eruption first showed itself in 1891, especially upon the anterior surfaces of the forearms and about the elbows, with a few scattered spots upon the knees. With the exception of those about the elbows, they all disappeared. In the present attack about one hundred and fifty lesions made their appearance upon the right arm, and about the same number upon the left; but in the latter there were none over the fingers or joints. About fifty lesions are present upon each leg, from the calf to the middle-thigh region. The face and eyelids are free. The size ranges from that of a pin's point to a pin's head. The color is yellowish, with a tinge of red. On pressure the former is intensified. The urine showed no sugar, but the report of the examiner was that it appeared "glycosuric." It contained twenty per cent. by bulk of albumin and a few granular casts. A photograph of the patient was shown.

In the discussion DR. DUHRING said he had recently seen a similar case, in which the diagnosis was difficult because of the smallness of the lesions, which disappeared under antidiabetic treatment.

DR. MORROW said that sugar was not always found in these cases. In some undoubted cases of this eruption, it could be discovered at one time and not at an-

other. It might be found only after the morning meal. Interstitial nephritis is common, but he had never known it to precede the glycosuria.

DR. FORDYCE reported a similar case, seen in Dr. Elliot's clinic.

DR. ALLEN said that if the urine was persistently examined in Dr. Robinson's case, he would expect sugar to be found eventually. He had seen instances of intermittent glycosuria.

DR. WHITE said that while the old English works laid much stress upon the association of xanthoma and jaundice it was in reality seldom observed. English physicians had told him that the combination was also in their experience exceptional.

DR. ALLEN said that he had observed an instance of most intense and long-lasting jaundice in the most extensive case of xanthelasma about the lids he had ever seen. The man died. The only post-mortem examination permitted was a small incision over the liver. A small piece of the latter, which was much enlarged, was taken, but was lost in the laboratory. Its surface was mottled and xanthoma was strongly suspected from its gross appearance.

DR. ROBINSON thought it remarkable that while diabetes was comparatively frequent, xanthoma was rare. When he reported his first case it was the tenth on record, and till now but twenty-nine have been recorded. The patient had a parenchymatous nephritis, but the speaker had never observed sugar in this condition.

Some Glycosuric Dermatoses.—DR. CHARLES W. ALLEN, of New York, read a paper with this title. The writer considered that while many different dermatoses depended upon glycosuria and disappeared when sugar was no longer present in the urine, the number of dermatological conditions which could be looked upon as peculiar to the disease diabetes was so limited that a class of diabetides could scarcely be said to exist.

Some unusual cutaneous eruptions occurring in subjects of diabetes were described, such as multiple areas of cutaneous gangrene, and states suggesting acne varioliformis and acne cachecticorum, with pigment spots and exaggerated hairy growths corresponding to the areas affected.

DR. WHITE said, in opening the discussion, that the writer had failed to mention that form of dermatosis which he regarded as characteristic, viz., the very acute eczema about the genitals, occurring especially in stout women. He also referred to an acute evanescent form of erythematous eczema, like that seen in association with œdema of the lower extremities. The skin furnishes a good nidus for the development of the furunculus coccus without the existence of a so-called diathesis.

DR. DUHRING had not found glycosuria in such frequent connection with furunculosis as some had.

DR. FORDYCE asked if the patient with xanthoma and discolored skin had presented symptoms of Hodgkin's disease.

DR. ALLEN said he had found no evidence of such a condition.

DR. MORROW said these eruptive troubles had been explained on the assumption that they were due to the local contact of saccharine urine, favoring fungous and parasitic growths. Others besides Dr. White had mentioned eruptions on parts remote from the genital region where there was no contact with saccharine urine. Sugar in the blood modifies its chemical properties and its power of maintaining nutrition of the tissues. It had been asserted that sugar was excreted by the cutaneous glands, producing irritation. Many eruptions could be explained by the foreign substance in the blood, just as in drug eruptions.

DR. WHITE spoke of grocers' itch, due to handling brown sugar.

DR. DUHRING thought the dermatitis due to the mite found in such sugar.

DR. DYER thought it a trade eczema due to the irritation of the sugar itself.

DR. WHITE said experiments with the sugar mites had given negative results.

DR. WINFIELD had observed that sugar workers who kept their hands out of the sugar water were exempt.

DR. ALLEN, in closing, said he had omitted to read that portion of his paper which touched upon the genital pruritus and dermatitis. He had not meant to imply that he always found sugar in furunculosis, but he always made it a point to examine for it. He agreed with Dr. Morrow that local contact of urine was the cause of eruptions about the genitals, but at a distance excretion by the skin would explain the irritation. Vergely had found two and a quarter grams of sugar in one hundred and ninety cubic centimetres of fluid collected from an ulcer on an œdematous limb showing such excretion.

Hypertrophic Rosacea (Pachydermatosis), Resembling Tubercular Leprosy, Cured with Thyroid Extract.—DR. DYER, of New Orleans, reported a case of this nature. The patient, aged sixty years, was suspected, from his appearance and from the fact of his living in a community where leprosy is endemic, of being a subject of this disease. The nodose appearance of the face was much that of the leonine countenance of tubercular leprosy, but the limitation of the affection to the face and to the dorsum of the hands furnished the first points which determined the exclusion of that disease from the diagnosis. The skin of the face was much thickened in rugæ, in mostly parallel lines, crossing each other at intervals of an inch or less apart, producing a tessellated appearance. There was extensive scaling and almost constant itching. The color was dull red. There were no tubercles nor telangiectases. The patient drank beer sparingly. The infiltration and thickening in regular nodosities suggested the name pachydermatosis. No treatment had influenced the condition, and after two months or more the reporter concluded that this case was identical with one depicted in the atlas of the St. Louis Hospital as hypertrophic rosacea, the early history being that of a progressive rosacea which had been neglected. Thyroid extract in five-grain doses three times daily was now ordered and for local use resorcin, $\mathfrak{v}$ i.; rose water, $\mathfrak{v}$ iv.; lanolin, ad $\mathfrak{v}$ vi. After two months of almost constant treatment there was decided improvement, the skin being soft and normal to the touch and the color being greatly improved both in face and hands. In July the patient was discharged cured after some three months of thyroid medication. Photographs showing the condition before and after were presented for inspection.

DR. WHITE said the report did not recall to his mind any ordinary case of pachydermia he had seen. He asked if there were other evidences, as myxœdema.

DR. DYER replied in the negative.

DR. DUHRING said the term pachydermia seemed appropriate, but he did not see how the diagnosis hypertrophic rosacea could be made.

Iodoform Dermatitis.—DR. FORDYCE, of New York, showed two water-color sketches of an unusual form of iodoform dermatitis occurring in a man with pulmonary tuberculosis and following the application of the drug to a contused finger. It consisted of large patches of grouped tubercles, papules, papulo-vesicles, pustules, and elevated erythematous spots, involving the hands, forearms, neck, and face. A colored drawing of an eruption resulting from the internal use of iodide of potassium was shown, in which almost identical regions were involved.

Multiple Papillomatous Tumors.—DR. FORDYCE then exhibited several colored drawings illustrating an unusual form of granuloma, occurring on the anterior surface of the leg, the popliteal spaces, the penis, the scrotum, and over the sacrum. The tumors developed on an eczematous surface and presented many of the features of mycosis fungoides.

DR. FORDYCE also showed colored drawings of cases of symmetrical keratosis of the cheeks, tinea barbæ, psoriasis of the palms, atrophy of the skin following involution of molluscum fibrosum tumors, congenital nævus of the eyelids, epithelioma of the scalp with papillary outgrowth, epithelioma of the auricle, mycosis fungoides in the stage of tumor development, lupus erythematosus of the cheek after frostbite, and a case of erythema multiforme of the arms, of toxic origin. Photographs of pityriasis rubra (of Hebra), ichthyosis, nævus papillaris, molluscum fibrosum, and of complete alopecia resulting from early syphilis were shown, together with a number of photomicrographs of pathological conditions.

The Relation of Dermatitis Herpetiformis to Erythema Multiforme and to Pemphigus.—DR. L. A. DUHRING, of Philadelphia, read a communication on this subject, of which the following were the conclusions: (1) Dermatitis herpetiformis is in most instances a disease with well-defined and tolerably constant clinical features. (2) In most instances it is more closely allied to erythema multiforme than to any other disease. (3) The bullous variety of dermatitis herpetiformis possesses features which resemble those of pemphigus vulgaris, from which latter disease, however, it differs in the peculiar inflammatory character of the cutaneous lesions, as well as in the tendency to polymorphism, in the irregular evolution of the lesions, and in its course.

DR. FORDYCE said we had been unable to classify recurring eruptions of multiform type frequently leaving pigmentations until we recognized this separate and distinct type of dermatitis herpetiformis, now generally accepted.

DR. JACKSON had been in accord with the writer's views. He believed many cases reported as pemphigus belonged to this class.

DR. WHITE thought the term multiformis far better, because of the great multiformity of the lesions and because of the variations assumed by the disease in different recurrences in the same individual. The term "herpetic" seemed a misnomer. No case he had seen presented an area which he would mistake for an expression of the lesions which characterize herpes, nor did we see the self-limitation of the lesions as in herpes. Many cases, too, have no suggestion even of herpes. He could not agree with the reader that individual cases could be so easily distinguished from pemphigus. In observing a case over a considerable period, we should always be able to make the diagnosis.

DR. ALLEN said the paper had cleared up one or two points about which there had been doubt as to Dr. Duhring's exact views. He had believed and expressed himself in writings that multiformis was the preferable term, since three or four primary lesions may appear together and none of them closely resemble herpes, and he had further suggested the general adoption of the designation "Duhring's disease," which would do away with all controversy as to the name. He knew of no reason why we should speak of lesions following certain nerves rather than lymphatics or blood-vessels.

DR. ROBINSON said that if the term dermatitis was to be used at all he was strongly in favor of using it in the connection in which Dr. Duhring had employed it. Dermatitis multiformis means nothing at all. He was astonished that Dr. Duhring should use the argu-

ment of the neurotic nature of the affection, as though it were an accepted view. It was an instance of choosing the name of a symptom for the name of a disease. He believed it most certainly a parasitic disease or a toxic disease manifesting itself through the blood-vessels or the nervous system.

DR. DUHRING, in closing, said he thought the causes varied. He could not state just what the causes always were. The name was important and he thought the "herpetiformis" more exact. Herpetiformity was an essential of the disease, but it did not mean that it resembled herpes or zoster. The original meaning was a creeping disease. Herpetiform expressed a broader meaning than herpetic. He admitted a relationship of pemphigus in symptoms and probably also in etiology. He had only said the cutaneous nerves were implicated, not that the eruption followed their course. Implication of the cutaneous nerves gives rise to the peculiar evidence described under the term "herpetiform."

Impetigo Contagiosa Universalis.—DR. C. W. ALLEN, of New York, read this paper. He based his remarks upon the case of a young girl whose vesiculobullous eruption, extending over almost the entire body, was shown in photographs presented. The lesions had begun to appear as vesicles upon the arm very shortly after vaccination, and from then until the patient was cured some nine months later had continued to crop out in various regions as bullæ extending at the periphery or drying down with formation of crusts, with smaller blebs or vesicles in their neighborhood. She was first seen four months after the disease began. There were infiltrated and pigmented areas where the lesions had existed. The disease bore a resemblance to pemphigus, and the same condition is called epidemic pemphigus or pemphigus contagiosus when a number of cases coexist. The diagnosis was based upon the benignity of the process, the non-effect of arsenic and internal medication, the origin in vaccination, and certain lesions upon the chin which were clinically identical with those of ordinary impetigo contagiosa. Cure was finally effected under the use of ichthyol in collodion as an occlusive dressing.

DR. DYER said he had been interested in the paper because it called to his mind a series of similar cases after extensive vaccination in New Orleans. In the first case he supposed the condition to be true dermatitis herpetiformis. The photographs exhibited are identical with those of his own case, excepting that in the latter the bullæ became hemorrhagic. The urine contained a large percentage of albumin. During two years there were recurrences of a true impetiginous type. He had seen three other cases, in only one of which the urine was free from albumin. Judging from Dr. Duhring's paper, perhaps after all the correct diagnosis was dermatitis herpetiformis.

DR. WHITE asked if there were any similar cases in the patient's immediate surroundings.

DR. ALLEN said there had occurred an almost identical case, as he had been told, in the same part of the city, and he had subsequently seen a number of impetigo cases near by and was told it was very common.

DR. WHITE said that cases in which there are widely distributed staphylococci present features very different from those here described. He thought it unfortunate that no examination had been made to establish the presence of the staphylococcus, about which so much had been said.

DR. DUHRING said no proof had been brought forward of contagion or of the existence of micro-organisms which militated against the diagnosis. From the photographs alone he would be inclined to make the diagnosis between pemphigus and dermatitis herpetiformis. In children the latter was milder than in adults, but there was a special tendency to bleb forma-

tion. He was strongly inclined to exclude impetigo contagiosa.

DR. ALLEN said, in closing, that he believed the bullous form of impetigo existed and that his was an example of such cases. There might be bullous lesions, but none such were present in this instance. The origin in vaccination, starting in the immediate neighborhood of the crusts, was a strong point in favor of impetigo. There was nothing in the distribution or in the appearance which could be described as "herpetiform," unless one spoke of the creeping undermining of epidermis in this sense. The element of contagion was lacking, but if we admit the possibility of accidental inoculation along with vaccination it seems not so important. The communication from one surface of the body to another by scratching, etc., was almost as good proof of its communicable nature as though transfer to a second person had been shown in the history.

He would ask Dr. Duhring if he regarded vaccination as an important etiological factor in dermatitis herpetiformis.

DR. DUHRING said he did not.

Election of Officers.—Dr. James C. White was elected *President*; Dr. Louis A. Duhring, *Vice-President*; Dr. John T. Bowen, *Secretary* and *Treasurer*.

The next meeting will be held in Washington, D. C., in connection with the congress of American physicians and surgeons.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-Fourth Annual Meeting, Held in Buffalo, N. Y., September 15, 16, 17, and 18, 1896.

First Day—Tuesday, September 15th.

THE association assembled in Ellicott Square, and its deliberations were presided over by Dr. Eduardo Liceaga, of Mexico, president of the superior board of health of that city.

DR. STEPHEN SMITH, of New York, the first president of the association, was introduced and made a few remarks with reference to the progress the association has made from its beginning.

DR. ERNEST WENDE, commissioner of health of Buffalo, cordially welcomed the association in behalf of the local committee of arrangements.

Report of the Committee on Car Sanitation.—This was read by DR. C. PROBST, in the absence of DR. G. P. CONN, of Concord, chairman. The report states that any one who takes an interest in car sanitation will soon become convinced that there is something lacking in the manner in which cars are cleansed and kept in condition for the travelling public. Ignorant and untrained help may and does destroy a great deal that should be cared for, and thus the expenses of this department are far beyond what is actually necessary.

Observations on the Cleaning of Railroad Passenger Cars.—By DR. DOMINGO ORVANANOS, of the City of Mexico. To afford any security against contagion or infection from railroad cars, it is necessary that the cleansing operations shall be carried out several times a day. To attain these objects, the author thinks passenger cars ought to be constructed in a manner very different from the present one. The bed clothing, including the blankets and curtains, should be changed daily, as well as the mattresses.

Possibilities of Contagion from Venereal Diseases in Railway Cars.—This paper was read by DR. TOMAS NORIEGA, of the State of Chiapas, Mexico, in which he cited the case of a married man, thirty years

of age, who arose from his berth in a Pullman car and, as was his custom, washed his face in the lavatory. Two days thereafter he felt the first symptoms of purulent ophthalmia, for which he consulted a physician. The patient was treated energetically, but in spite of all efforts the right eye was lost. Other similar cases were reported.

DR. FREDERICK MONTIZAMBERT, of Montreal, general superintendent of the quarantines of the Dominion of Canada, presented the report of the committee on steamboat and steamship sanitation.

Infectiousness of Milk.—**DR. JAMES KENNEDY**, of Des Moines, Ia., read a paper on this subject. Cow's milk alone was considered, since no other kind of milk is used by many infants and adults, and since it is the almost universal and, under proper conditions, the best substitute for human milk in the feeding of children. In Berlin, in giving the certificates of death of children under one year, the fact must be stated as to whether the child was fed from the breast or brought up artificially. In ten thousand deaths thus reported, it was found that two-thirds, or seventy-six hundred and forty-six infants, were artificially fed. The author emphasized the importance of a sanitary inspection in addition to, if not to the exclusion of, the mere commercial examination.

Report of the Committee on Animal Diseases and Animal Food.—This was read by the chairman, **DR. D. E. SALMON**, of Washington, D. C. Animal diseases are now more intelligently managed by sanitary officers than ever before, and the meat-inspection service has been steadily extended and perfected. Outbreaks of anthrax among the domesticated animals are apparently becoming more frequent. The contagion once introduced into a pasture remains indefinitely. A disease so fatal to man and beast should be promptly repressed whenever it makes its appearance, and precautions should be observed to prevent infection of new territory.

Pathogeny, Etiology, and Prophylaxis of Typhus.—**DR. FRANCISCO DE P. BERNALDEZ**, of Mexico, contributed a paper on this subject. This disease arises from a microbe not as yet discovered. Throughout all the districts which are called the hot country in the Mexican republic, the infection of typhus does not exist, while in the temperate regions at a higher elevation it occurs in endemic form.

Report of the Committee on Nomenclature and Forms of Statistics.—By **DR. SAMUEL W. ABBOTT**, of Wakefield, Mass., chairman. The report dealt with the need of a uniform system of classification and nomenclature. Before advising the general acceptance of any one system for general use, the committee recommended that the association collect and compare the systems now in use and employed by the different national, State, and municipal authorities in this country, in order that these may also be compared with the systems in use in other countries, so that a general system can be recommended for adoption throughout the States and countries within the bounds of the association.

The Nomenclature of Diseases and Forms of Statistics.—**DR. EDUARDO LICÉAGA**, the president, read a paper on this subject. The board of health of Mexico City had, from the year 1879 up to the year 1887, classified the diseases resulting in death in a certain number of groups. In the year 1888 he, as president of the board, proposed the adoption of the provisional nomenclature adopted by the Royal College of Surgeons of London. This nomenclature was adopted because it was the one then followed by almost all the English-speaking nations, and so the Mexican tables of mortality might be compared with those of such nations.

On the Need of Uniformity in the Meaning of

the Term Stillborn.—By **DR. JESUS E. MONJARAS**, of San Luis Potosi, Mexico. The laws of different countries were cited by the author, after which he proposed the following: (1) That there shall be included under the term stillborn all children of more than six months of intra-uterine life that are born dead. (2) That there be added to the nomenclature of the causes of death the term that shall represent all children that die within seventy-two hours after birth without known cause, and that they be designated by the term "died at birth without known cause." (3) That the committee on nomenclature of diseases and forms of statistics be authorized to recommend this modification of the existing nomenclature in all the countries of the American continent. (4) That these modifications once adopted in said continent, the same would doubtless be accepted in Europe and elsewhere.

Dengue.—A paper on this subject was read by **DR. HENRY D. HORLBECK**, of Charleston, S. C. The disease was defined, after which the author said the object of the paper was to put on record a brief account of a widespread outbreak of this malady which occurred in Charleston in 1895. During its prevalence from July until November, it is estimated that fifty thousand of the inhabitants were afflicted with the disease. Men and women seventy years of age and infants had it, and yet the malady was not prevalent a few miles away from them. Notwithstanding the suddenness of the onset and severity of the attack, death is rare.

Municipal Responsibility for Healthy Schoolhouses.—**MRS. ELLEN H. RICHARDS**, of Boston, contributed a paper on this subject. Local agitation of this question might do some good, but to the author it seemed as if the time had come for some concerted action, compelling city authorities to keep schoolhouses in good condition. A most efficient way would be to bring to bear the power of the law, and to insist that such buildings as are flagrant violations of the law shall be closed, as private buildings would be.

Addresses were delivered by the mayor of Buffalo and the **REV. THOMAS SLICER**, both of whom spoke of the benefits of sanitation.

Presidential Address.—The president, **DR. LICÉAGA**, then delivered his address. He first thanked the members for the distinguished honor conferred upon him, after which he said that the preservation of health, the prolongation of life, and the physical improvement of the human race were the ideal principles that ought to be kept in view. Coming to the question of epidemics, he stated that they can be suppressed at their inception by isolating the first patients and disinfecting the objects which they have contaminated, whether these objects be the clothes they have used, the furniture found in their respective rooms, or the rooms in which they were kept during the disease. Isolation in cases of diphtheria must be absolute and complete. A proposition which demanded special study was the technique of disinfection. Lastly, the speaker cited examples to show the advisability of organizing a committee to study the periods during which each contagious disease is transmissible, and the time during which every patient who has suffered from such disease is dangerous to the community.

Second Day—Wednesday, September 16th.

Report of the Committee on the Disposal of Garbage and Refuse.—This was presented by **MR. RUDOLPH HERING**, C.E., of New York City, chairman, and was followed by a paper entitled "Disposal of the Garbage and Waste of the Household," by **COL. W. F. MORSE**, of the same city. In considering the matter of the final disposition of garbage, the author said that no record of methods could be complete unless

those means were considered by which the waste of the family was destroyed in the home where it was produced. An apparatus in the form of a carbonizer for the disposal of garbage was described.

A Plea for the Domestic Disposal of Garbage.—DR. N. E. WORDIN, of Bridgeport, Conn., read a paper with this title. Fire is the best destroyer. It leaves no filth and no germs behind. The different methods of disposing of garbage were tabulated as follows: 1. The most wasteful—sea disposal. 2. The most offensive—hog feeding or fertilization. 3. The most economical to operate—reduction. 4. The most sanitary and complete—cremation. Reduction and cremation were the only methods worthy of consideration for any city.

DR. WILLIAM S. TREMAINE, of Buffalo, explained the results of practical experiments with one of the garbage crematories in Buffalo. This crematory successfully disposes of garbage and excrement without occasioning any odor.

Report of the Committee on Transportation and Disposal of the Dead.—By the chairman, DR. CHARLES O. PROBST, of Columbus, O. The committee is of the opinion that it is quite possible to so prepare, with promptitude and but little expense, a body dead of infectious diseases as to make it transportable without any danger of transmitting infection; and it is the duty of the association to develop the simplest methods by which this desirable end can be obtained, in order that the sentiment of respect for the dead may be maintained without any danger to the living. If, however, all dead bodies are to be allowed transportation, it will be necessary to provide that the preparation of bodies dead of contagious disease shall in each instance be under the direct supervision of the health authorities.

The Quick or the Dead.—DR. BENJAMIN LEE, of Philadelphia, read a paper with this caption. Health authorities should be very slow in relaxing any of the precautions and restrictions at present in force attending the transportation of those dead of contagious diseases. He thinks the true solution to the question of transportation is to be found in the cremation of all bodies dead of contagious diseases.

On Measures for the Prevention of Blindness.—By DR. AUGUSTINE CHACÓN, of the City of Mexico. Statistics, cited by the author, prove that a great deal more than half of the cases of blindness might very probably have been avoided, if proper measures had been taken in time. The two diseases of the eyes which cause the loss of sight in the largest number of patients were atrophy of the optic nerve and purulent ophthalmia. These two diseases were considered at length. Special attention ought also to be given to hygiene of the sight in schools.

Miasmatic Fevers in the State of Sonora.—DR. ALBERTO G. NORIEGA, of Mexico, read a paper on this subject. The author spoke of the origin, treatment, and some of the peculiarities of the symptomatic characteristics of fevers of miasmatic origin in the State of Sonora. He proposed the following prophylactic measures: 1. The planting of thick woods around the township, with the idea of suppressing the paludic miasma where the trees grow. 2. The houses ought to be built on the highest places, in order to keep them as far as possible out of the reach of the gases from the pools and marshes. 3. The front of the houses must not face the direction of the dominant wind, and the houses themselves ought not to be in the way of the winds coming from the pools. 4. To avoid the watering of the floors, in order to maintain the interior of the houses as dry as possible. 5. The workmen in the fields must not commence their work until the sun is well up, and they must retire from the fields before the sun sets.

Summary of Sanitary Legislation in the State of Mexico.—This paper was read by DR. M. ALVAREZ, of Mexico. The author said that the philosophy of sanitary legislation rested on three bases: 1. Those which attempt to endow the individual with good health. 2. Those which take precautions against diseases of all kinds. 3. Those which require the partial sacrifice of individual liberty in favor of the general community. The author then entered exhaustively into a consideration of drinking-waters, vaccination, and vaccination laws, paying particular attention to the obligatory-vaccination law of Mexico.

Obiter Dicta Concerning Sanitary Organization.—DR. A. WALTER SUITER, of Herkimer, N. Y., read this paper. He said a system of health administration without effective organization was like a ship without a rudder, subject to the mercy of every pestilential storm. Dr. Suiter made a strong plea for an arrangement so systematized that sanitary direction may be administered in the most practical and advantageous manner without conflict of authority. The public should be educated to a point of proper appreciation of the importance of the service required.

Some Thoughts Relative to Sanitary Legislation.—DR. U. O. B. WINGATE, of Milwaukee, Wis., read a paper with this title. The author believes that laws pertaining to sanitation should differ very materially from other laws, inasmuch as they voice a scientific fact, and if applicable in one locality they should be also applicable in all localities. Attention was directed to the great need of a system of statistics, not only pertaining to births and deaths, but to sickness or the prevalence especially of contagious and preventable diseases. A strong plea was made for a department of public health at Washington.

The Sanitary Administration of Unincorporated Districts.—In a paper with this title, DR. HENRY MITCHELL, of Trenton, N. J., presented the following propositions: 1. By law provide that in each township, or other local political division outside of municipalities, the sanitary authority should be exercised by one official. 2. The local health officers should be selected under civil service rules, and their term of office should be five years. 3. The examination of applicants for the office of township health officer should be conducted by the State board of health. 4. The appointment of the health officer in each township should be made by the governing body of the district, from an eligible list to be furnished by the State board of health. 5. No health officer should be removed except for cause, and vacancies should be filled for the unexpired term in the manner provided for original appointments. 6. Local health officers should be required to conduct all of their official operations in accordance with rules and regulations approved by the State board of health, and they should also make weekly reports of their doings to said board and annually to the local governing body. 7. The local health officer should be paid for his services by the local governing body. 8. All suits for the violation of any local sanitary rule, regulation, or ordinance should be brought at the instance of the local health officers, and they should be prosecuted by the district attorney or prosecutor for the county; but no such suit should be begun until the necessity for its being instituted has first been agreed to by the State board of health.

Report of the International Committee on the Prevention of the Spread of Yellow Fever.—DR. FELIX FORMENTO, of New Orleans, read this report which embodied the following recommendations of the committee: 1. Extreme measures of local sanitation in yellow fever foci. Modification of the soil, improvement of harbors, etc., by all means known to sanitary engineering. 2. Putting in perfect sanitary condition all home seaports and towns most ex-

posed to infection. 3. A rigid and efficient system of quarantine against the introduction of the disease. 4. Abolishing forever the abominable system of interment and disinterment practised in Spanish-American countries. 5. Wherever practicable, yellow-fever hospitals should be established beyond or above yellow fever foci. When this cannot be done, these hospitals should be established at a distance from centres of population in a desirable locality and perfectly isolated. 6. Compulsory cremation of all bodies of persons who have died of that disease, and incineration of all infected material.

The Study of Yellow Fever from a Medico-Geographical Point of View.—DR. LICÉAGA said that this was the fourth paper he had presented on this subject, and his object was to enable the association to realize the true situation of the Mexican republic as regards yellow fever. With the aid of facts, he disproved the erroneous idea which for so many years had existed, that it was a country in which this disease was always found throughout the entire extent of its territory.

A Contribution to the Study of Yellow Fever in Relation to Epidemics in Córdoba.—DR. G. MENDIZABAL, of Orizaba, Mexico, followed with this paper. The author presented a *résumé* of the number, intensity, duration, and mortality of each of the epidemics of yellow fever which had desolated during three centuries the above-mentioned city. This city, besides its climate and soil, its constant humidity, its proximity to Vera Cruz, and many other causes which favor the propagation of the morbid germs, has a great scarcity of potable water of the requisite purity. It is the duty of the municipal authorities to improve the hygienic conditions of the people of this city, to provide them with potable water, to make the soil sterile to the germs of the disease, and thus forever close the doors against this desolating plague.

Isolation Hospitals.—DR. JOHN L. LEAL, of Paterson, N. J., read a paper, in which he spoke of the utility of isolation hospitals in the restriction of preventable diseases, and illustrated his remarks by views and plans of the Paterson Isolation Hospital.

Third Day—Thursday, September 17th.

Pollution of Water Supplies.—MAJOR CHARLES SMART, surgeon of the United States army, Washington, D. C., chairman, read the report of the committee on the pollution of water supplies, in which he referred to the bacteriological convention held in New York City and the work accomplished by it, and said that when a description of the standard methods recommended by this convention is in the hands of the bacteriologists of this country, the committee will then be in a condition to define its lines of action for effecting an organization for co-operative work, as suggested at Montreal.

DR. PETER H. BRYCE, of Toronto, chairman, presented the report of the committee on river conservancy boards of supervision. The committee was not as yet prepared with such data regarding individual cases of pollution to present practical suggestions with reference to such a board for any particular stream, but desired, by laboring in conjunction with the committee on pollution of streams and with various engineering associations to collect material which might give to the committee's report in another year some practical value.

DR. CHARLES N. HEWITT, of Red Wing, Minn., as chairman, presented the report of the committee on protective inoculations in infectious diseases.

The Serum-Diagnosis Test for Typhoid Fever.—By DR. W. JOHNSTON, of Montreal. The author demonstrated a modification of Vidal's method of serum

diagnosis in this disease. He considered the test very reliable from a diagnostic point of view and thought it would prove of considerable value for public-health work, and that it would lead physicians to report their cases more frequently and promptly.

Prophylaxis of Typhoid Fever was the title of a paper by DR. JOHN E. WOODBRIDGE, of Cleveland, O. Typhoid fever was characterized as a water-borne disease, and every attack was considered the child of a previous one and was *prima facie* evidence that the victim had eaten or drunk unsterilized human excrement or some of the products thereof. The government of the United States, he said, will not have discharged its whole duty to the people, will not have attained the zenith of its greatness, until through a department of public health, aided by wise legislation, it has taken every possible precaution not only to protect the health and foster the highest physical development of its citizens, but to guard well the purity of the air they breathe, the food they eat, and the water they drink.

DR. F. C. ROBINSON, of Brunswick, Me., read a paper in which he spoke of the practical use of formic aldehyde as a disinfectant.

DR. E. A. DE SCHWEINITZ, of Washington, D. C., demonstrated and exhibited a convenient lamp for generating formaldehyde gas; while DR. J. J. KINYOUN, of Washington, D. C., followed with a preliminary note on the use of formaldehyde for room and car disinfection. His results so far obtained from its use were very gratifying. Dr. Kinyoun also exhibited and described an apparatus of his own design for generating this gas.

Malaria.—Two papers were then read, one on the prophylaxis of paludism, by DR. A. R. ERDOZAIN, of Mexico, and the other on paludism in the State of Morelos and its prophylaxis by sanitary measures, by DR. A. GAVINO, of Mexico.

Public Health in Tabasco.—DR. JUAN MULDSON, of Mexico, read a paper on public health in Tabasco. He presented the following conclusions: 1. The sanitary condition of Tabasco in general is good. 2. Paludism is the principal disease, but it is satisfactorily treated. 3. Yellow fever is not endemic; it occurs in isolated cases, being generally imported and not finding a good soil for its propagation. 4. Isolation and other hygienic measures have successfully prevented propagation of the disease. 5. Natives are not so easily attacked by yellow fever as foreigners are, and people accustomed to the climate who have lived there for many years also acquire this immunity. 6. The climatological conditions notably modify the clinical history of certain diseases, among which forcibly calling our attention is the benign course of septicæmia.

Prevention of Diphtheria.—DR. J. J. KINYOUN, of Washington, D. C., chairman, presented the report of the committee on the cause and the prevention of diphtheria. The committee recommends the following:

1. That there should be uniform rules and regulations adopted by all the States and provinces for the prevention and control of diphtheria. The several governments should assume the responsibility and act in unison in preventing the spread of the disease from one country to another and assume authority over interprovincial and interstate communication.

2. That it should be the duty of the health authorities to provide facilities for determining the diagnosis in all suspected cases by the establishment of inexpensive laboratories for each health jurisdiction: to agree upon a system and means of transmission of material for diagnosis through the mails.

3. Compulsory notification of all suspected cases and the abolition of the terms croup and membranous

croup, unless diphtheria has been excluded by culture and microscopic examination.

4. Compulsory isolation of all cases, domiciliary or in hospital, until the recovered cases show the absence of the diphtheria bacillus.

5. That the medical inspection of schools should be inaugurated under the direction and supervision of the health authorities, by making daily inspections of all school children in the larger cities for the detection of infectious diseases. (The plan advocated by Dr. S. H. Durgin, of Boston, at the last meeting of the association, was highly commended.)

6. School buildings, books, etc., should be subjected to a reliable method of disinfection at least once a month, and oftener if suspected of being infected.

7. The early treatment of those ill with diphtheria with antitoxin, the administration of preventive doses to those who have been exposed to infection and have the bacilli in their throats.

8. Prompt and effective methods of disinfection of infected articles and apartments, to be carried out under the supervision of the health authorities.

Diphtheria in Chihuahua.—DR. M. MARQUEZ, of Mexico, contributed a paper with this title. He said that diphtheria was one of the infecto-contagious diseases which was most observed in Chihuahua, and in such a degree that it sometimes caused a panic among families. The author formulated twenty-four rules to be carried out to prevent the spread of the disease.

Bacteriological Diagnosis as Governing the Admission and Discharge of Patients in Diphtheria Hospitals.—By DR. E. B. SHUTTLEWORTH, of Toronto. The isolation hospital at Toronto was established in 1891, and up to June 30th last, there were admitted one thousand six hundred and ninety patients said to be suffering from the disease. Diagnosis by bacteriological methods was begun in February, 1895, and since July of that year the discharge of patients had also been governed by this means of investigation. The statistics for this period covered five hundred and sixty-five cases, and when compared with those for the preceding time, afforded an opportunity for ascertaining the practical value of bacteriology when applied to the purposes indicated.

DR. CHARLES N. HEWITT, of Minnesota, presented the report of the committee on causes and prevention of infant mortality.

The Mortality of Children, Its Causes, and Means of Diminishing It.—DR. S. GARCADIEGO, of Mexico, followed with a contribution on this subject. The speaker classified the causes of mortality of children under three heads—crime, carelessness, and ignorance. The author believes that the mortality among children can be diminished by the institution of lying-in hospitals or obstetrical departments, by which means it has been proved that infanticide nearly disappears, and also by establishing orphanages and homes for foundlings under the care of the government, and of religious people. In each of these asylums a limited number of children should be allowed in order to be properly cared for and attended to. For the feeding of infants in these institutions, the mother's milk should be replaced by that of the goat, or other nearly as proper as the former, using the utmost care in the cleaning of bottles. Mothers who abandon their children should be severely punished.

DR. FELIX FERMENTO, of New Orleans, presented the report of the committee on the use of alcoholic drinks, which was substantially that presented last year at the Denver meeting.

The Bicycle in Its Sanitary Aspect.—DR. ALBERT L. GHON, of New York, read a paper on this subject. The author criticised the posture and saddles used by riders of the bicycle. After presenting arguments for and against the bicycle, he ventured the prediction

that a light three or four wheeled vehicle, propelled by some easily managed motor, inexpensive enough to be generally available, would be the means of progression for pleasure purposes in the future, covering long distances without fatigue, permitting sight seeing and outdoor exposure without labor, and adding the charm of companionship and participated enjoyment, while the rational instrument of exercise for exercise's sake alone would ever be a pair of sturdy human legs.

DR. H. L. CHASE, of Brookline, Mass., read a paper on public bathing-establishments and gave a description of the new public bath in Brookline; while DR. W. H. TOLMAN, of New York, gave an illustrated lecture on public baths.

DR. CARLOS SANTA MARIA, of Durango, Mexico, read a paper on the part that public instruction should play in the way of precaution against contagious diseases. It was a plea for the general teaching of the elements of hygiene in the public schools.

Fourth Day—Friday, September 18th.

At this session the following papers were read: "Report of Committee on the Relation of Forestry to Public Health," by Prof. R. C. Kedzie, of Lansing, Mich.; "Report of Committee on Transportation of Diseased Tissues by Mail," by Dr. Henry Mitchell, of Trenton, N. J.; "On Statistics of Vaccination and Mortality from Small-pox in the City of Mexico," by Dr. Jose Ramirez, of Mexico.

DR. A. N. BELL, of Brooklyn, N. Y., read a paper on drunkenness, which he considered as a vice, and said that it should be so treated.

Protection of the Innocent from Gonorrhœa.—DR. F. C. VALENTINE, of New York City, read a paper on this subject. He said that if justification were needed for the discussion of this matter, it could be found in the statistics of the German empire for 1894. These show that of the women who died of uterine or ovarian diseases, eighty per cent. were killed by gonorrhœa. They further show that of children hopelessly blind, eighty per cent. went into a life of darkness from gonorrhœa. Gonorrhœal patients should be educated in incontrovertible facts, the physician ever choosing terms within the range of their intelligence.

Several other papers on the programme were read, some of them by title.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. H. B. Horlbeck, of Charleston, S. C.; *First Vice-President*, Dr. Peter H. Bryce, of Toronto; *Second Vice-President*, Dr. Ernest Wende, of Buffalo; *Treasurer*, Dr. Henry D. Holston, of Brattleboro, Vt.; *Secretary*, Dr. Irving A. Watson, of Concord, N. H.

Place of next meeting, Philadelphia, 1897.

Masturbation and Spermatorrhœa.—I do not believe it safe for a physician to prescribe fornication. It is not safe nor curative, apart from the moral aspect of the matter. It has always struck me also as pretty small business, for a man to purposely select a wife to relieve him of the results of a weak will and vicious sensual indulgence. If marriage comes in the natural course of events, as it often does, so much the better. But to select a wife as a remedial agent for masturbation is unjust to the woman and a confession of moral and mental feebleness. Man is distinguished from the brute by his self-control. Let him bear the fact in mind and raise himself by a determined effort of the will. Pure thoughts and chaste associations, vigorous physical exercise, and a resolute effort to act a manly part will always be successful.—DR. CHARLES L. DANA, *Text-Book of Nervous Diseases*, p. 460.

Therapeutic Hints.

Cardialgia of Hysteria and Neurasthenia.—Tincture of piscidia erythrina in daily dose of twenty drops.—*Deutsche med. Woch.*

Clinical Thermometers should always be cleansed with antiseptic care after using. This is neglected by many physicians, even after use in the mouths of patients ill with infectious diseases.

Dyspepsia.—

R Acidi hydrochlor. dil. 3 ss.
Tinct. nucis vom. 1 j.
Liq. potass. arsen. gr. lxxij.
Ess. of pepsin q. s. ad 3 vi.
M. S. Two teaspoonfuls in water after meals.

Amenorrhœa.—

R Aloes pulv.,
Ferri sulphat. exsic.,
Terebinth. alb. aa gr. xv.
M. et ft. capsul. No. xvi. S. One capsule an hour after each meal.

Much better effects are obtained from the iron by giving one hour after meals instead of immediately after.—DR. PARVISS.

Seasickness.—

R Cocain. hydrochlor.,
Ext. opii aa gr. iss.
Powd. marshmallow root. q. s.
Mix and divide into pills No. x. S. One pill every second hour.

Hyperidrosis of the Feet.—

R Liquor. ferri chloridi 3 i.
Glycerini 3 iiss.
Olei bergamotte 3 v.
M. S. Apply topically with a brush.

—DR. LEGOUX, *Deutsche med. Woch.*

Chronic Pyelitis when Pain is Present.—

R Venice turpentine,
Powdered camphor aa 3 iss.
Extract of opium gr. v.
Extract of aconite root gr. iij.
Mix and make into twenty pills. One pill to be taken every eight hours, and at the same time a small glassful of infusion of uva ursi, slightly sweetened.

—DR. A. ROBIN, *Progrès Médical.*

Epilepsy.—

R Codeinæ 3 i.
Potass. bromid 3 ij.
Infus. adonis vernalis. 3 iv.
M. Dose: From half a teaspoonful to a teaspoonful thrice daily.

—*Gaz. hebdom. de Méd. et de Chir.*, 1896, No. 17.

Nettle Rash.—

R Sugar of lead gr. xv.
Dil. hydrocyanic acid 3 iv.
Alcohol 3 viiss.
Distilled water. q. s. ad 3 ij.
M. S. To be applied on cotton wool.

—*Dublin Journal of Medical Sciences.*

Broncho-Pneumonia in Children.—

R Sodii benzoatis gr. viij.
Ammonii acetatis gr. xxiv.
Spiritus vini (cognac) 3 ij.
Misturæ acaciæ,
Syrupi simplicis aa 3 iss.
S From one-half to one fluid drachm every two hours.

—DR. MARFAN, *Rev. Internat.*

Ichthyol Varnish.—

R Ichthyol 25 parts.
Carbolic acid 2 1/2 "
Starch 50 "
Water 22 1/2 "
Dissolve the ichthyol and carbolic acid in water with heat, then add the starch.

—UNNA.

Influenza.—Creosote, fifteen to seventy-five minims daily.—ISELIN.

Lympho-Sarcoma.—Full doses of arsenic.—SCHLESINGER.

Lupus Erythematosus.—Continuous large doses of arsenic up to the point of systemic poisoning effects.—HUTCHINSON.

Pemphigus.—Treat locally as a burn. In acute pemphigus, sulphate of quinine. If patient is robust, blood-letting. In chronic pemphigus, tonics.—CHAMBERD.

Hydrotherapy has proven successful.—HEBRA.

Pruritus Ani has become a frequent affection among bicyclists. Wash frequently with alcoholic lotions; change linen often. In severe forms apply a solution of caustic potash.—STAFFORD TAYLOR.

Chlorosis.—In true idiopathic chlorosis, when iron is ineffectual, sulphur will produce a marked amelioration. After using sulphur, iron can again be resorted to, and it becomes very beneficial.—DR. SHULTZ, *London Medical Times.*

Conjunctives and uterine chloasmata are improved by:

R Aq. oxygenat. 20-40 gm.
Vaseline 20 "
Lanolin 10 "

Pruritus Vulvæ.—After local bath apply:

R Ex. cannabis ind. 2 parts.
Pulv. zinci oxid. 6 "
Potass. brom. 10 "
Glycerite of starch. 30 "

Hæmatemesis.—

R Pulv. plumbi acetatis 0.20 cg.
Morph. hydrochlorat 0.10 "
Pulv. sacch. alb 5. gm.
M. et ft. cht. div. No. x. S. One every two hours.

—BAMBERGER.

"L" Line Favorite for Burns.—

R Lanolin 1 part.
Lard 2 parts.
Lime water 3 "
—ALLEN.

Borosalicylic Cream.—

R Borosalicylate of sodium 20 gm.
Glycerole of arnica 40 "
Lanolin 18 "
American vaseline 22 "
—BERNEGAW.

Hemorrhage after Tooth Extraction.—Ferripyrin (a combination of antipyrin, sixty-four per cent., and chloride of iron, thirty-six per cent.) not only stops bleeding, but diminishes the pain when applied by means of a pledget of cotton.—FROHMAN.

Guaiaicol as an analgesic should be mixed with an equal part of glycerin, and covered with impermeable tissue to prevent evaporation. To secure antithermic results, it must be used pure or in a vehicle capable of being absorbed by the skin.—FERRAND.

A New Thermometer without visible scale until the tube is covered with an outer case has been presented by Dr. Mercier to the Zurich Medical Society. It is intended for use in cases of inquisitive patients when it is thought best that they should be kept ignorant of their thermic condition.

Prolonged Gestation.—Reckoning from the cessation of the last menses, the first feeling of life, and the objective signs, Dr. Szaszy reports a case in which gestation lasted three hundred and thirty days. The child was normally developed, and forty-nine centimetres long.—*Gyogyaszat*, 1894, No. 39.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WATER FAMINE ENDS—SANITARY INSTITUTE—
OFFICERS OF HEALTH—PORT SANITARY AUTHORITIES
—LAWSON TAIT ON VIVISECTION—MRS. TAIT ON
THE MATERNAL EXPRESSION—ARMY SURGEONS.

LONDON, September 11, 1896.

A RAINY week has put an end to the so-called water famine, which I have previously mentioned. It is to be hoped that the company will not be allowed to escape its responsibilities, for this is the third time in 1895-96 that it has failed in its duties. When the contract to supply is broken, surely payment should not be expected; and in the case of such a necessity as water, a serious failure should entail forfeiture of the monopoly. A representative of the *Times* has rather taken the part of the company, and harped on the wastefulness of the locality and the necessity of cisterns. He does not seem to know that household cisterns have long been tabooed by sanitarians, and talks of fifteen gallons daily per head as a sufficient supply. New York, which has, I believe, between eighty and ninety gallons, would demur to his estimate. Why, it takes thirty to forty gallons for a comfortable bath. The East London Company has failed again and again. There is no need of delay for inquiry. The time for action has come, and their monopoly should be ended. The water question must come before Parliament again.

The Congress of the Sanitary Institute, of which I reported the opening by the Duke of Cambridge, was fairly successful. Milk supply, water supply, the grievances of sanitary officers, the need for a minister of health, and various similar subjects were discussed. Drs. Waldo and Walsh urged that medical officers of health should devote all their time to the duties of the office. Professor Corfield held that compulsory vaccination ought to be strictly enforced, in order to prevent the spread of the most dreadful infection the world has seen. Earl Percy, the new president, said he always thought after one fine it would be better to send a recalcitrant to prison, which would show whether his objection was really conscientious. Dr. Newton also spoke on this subject. Bovine tuberculosis was treated by Mr. W. Hunting, ex-president of the Royal College of Veterinary Surgeons, who ably argued that it was absurd to try to protect the public by inspecting meat and milk while doing nothing to control the source of infection in the animals from which the meat and milk are obtained.

The conference of officers of health was presided over by Dr. A. Hill, who pointed out that diphtheria is increasing in this country, and that this is the more important, inasmuch as the proportion of this disease to small-pox, measles, scarlet fever, whooping-cough, and typhoid is also increasing.

The conference of port sanitary authorities was presided over by the chairman of the port of London authority, who pleaded for a wider recognition of the work of those who were keeping the front door of the country against the importation of infectious diseases.

Mr. Lawson Tait has long been numbered among the opponents of experiments on animals with a view of applying the results to surgery. Such a course, he considers, would lead to serious error. He has now cast in his lot more decidedly with the antivivisectionists. Their magazine, *The Animal's Friend*, for August, opened with an article by Mr. Tait, entitled "Why I Oppose Vivisection." He says Syme and Fergusson, who differed whenever they could, were right when

they asserted that surgery had in no way been advanced by experiments on animals. He then observes that the opinions first enunciated by these eminent surgeons, and entirely shared by himself, "have since their time slowly percolated through the profession and will some day soon be completely recognized by the whole body officially." The last word scarcely adds to the value of the assertion, as we have no official interpreter of the whole body; and whether the "some day" will be "soon" is open to question. Then comes the statement that the governing influence of the Royal Society has been the biological school, and of late years this may be admitted; as may, perhaps, the accompanying statement that hospital physicians and surgeons covet the F.R.S. less than formerly. Mr. Tait goes on: "This, however, has still to be said, as it might have been said any time this last twenty years, that any one holding the views I do on the subject of experiments on animals might as well stand for the presidency of the United States as for the fellowship of the Royal Society—and of this no secret is made." The introduction of this personal allusion will bring a grim smile to the faces of some of his enemies, who may exclaim, "*Hinc ille lacryme*," but Mr. Tait cares for nothing of the kind, and is not likely to mince his words. This he shows a little further, when, having quoted Sir Edwin Arnold's speech from the *British Medical Journal*, he adds: "The editor of this journal is a Mr. Abraham Hart, a Hebrew with a past, and his rancor on the subject . . . and his animosity toward those who support the movement in any way, has been most remarkable, even among those of his race who are noted . . . for their support and their practice of vivisectional research." This fling would, perhaps, have been as well reserved for the ethical meeting at Carlisle.

Passing by all hard words, which will have no more effect on his opponents than on himself, I find little in Mr. Tait's contribution to *The Animal's Friend*, until he mentions his position on ectopic gestation and his views concerning the uncalled-for experiments of a German vivisector. Certainly here Mr. Tait speaks to the point. But his opponents will draw a distinction between the use and abuse of experimentation.

He says he does not take up the sentiment of the question. This point, however, is illustrated by his wife in a subsequent article in the same magazine. Mrs. Tait gives some interesting reminiscences of her sensations and of her cats. She also professes to recognize a "peculiar look impressed by maternity upon the female of all animals." This "special expression is common to us and the lower animals," says Mrs. Tait, and she sees it in the Madonnas of A. del Sarto and of other painters, as well as in the cold marble of the wolf suckling Romulus and Remus, at Florence. I cannot emulate Mrs. Tait as a judge of physiognomy, but have, I fancy, quite as kindly feelings toward animals. But I draw the line where perhaps she would, too. A lady living near me treats a cat to fresh sole and other expensive articles of diet daily. That, too, when human children starving do not touch her sympathy. Truly, human beings are strange creatures!

I hear that between sixty and seventy army medical officers, having completed their six years' foreign service, are now entitled to be relieved. With the dearth of doctors at home and only half the number of candidates for the vacancies, the officials will be puzzled to make proper provision. It is not the first time such a deadlock has been brought about by the stupidity of military prejudice. The *Admiralty and Horse Guards Gazette*, which reflects the follies of so-called combatants, has lately pretended that the army surgeons are too brusque to be favorites. The discovery is worthy of the combatant who "seldom drinks and never

swears," or of the journal that is content to play sycophant to snobs.

The contest with clubs¹ still goes on with varying fortune. In some places the profession has triumphed, but only where a united front has been maintained.

THE SECOND INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The medical profession is, perhaps, the most truly co-operative international body on earth. Its members all work toward one aggregate result and rule of practice. When, therefore, the full report of the Geneva Congress is published, we shall have the latest opinion of the best professional minds of the world on the subjects discussed.

You will already have received the special report of proceedings. But until the volume of transactions arrives, it is premature to estimate the scientific result of the meeting. It must suffice to touch its surface phases.

"Scientists are all compatriots," said Péan, in his toast; and this sentiment was realized thoroughly in the social aspect of the congress, though hardly in the set meetings. Some of the *contretemps* here were almost farcical. In the first place, there was no discussion. The papers on the set subjects were printed and distributed in advance, and then rapidly read in the mother tongue. Nearly all the members, other than the compatriots of the speaker, would scamper at the opening of an uncomprehended paper—excepting, perhaps, our own courteous countrymen, whose sense of decorum made them more than attendants upon a mere national section of an international congress.

Then, the "ten-minute" discussions, so-called, were also short essays printed and distributed beforehand; giving, it is true, the author's opinion, but in no sense debating previously expressed views. The one virile exception was Péan's extempore response to Doyen, of Rheims, who claimed priority over the giant hysterectomy in describing the vaginal operation. Here the interest was real, instant, and international, and reached a climax in the trumpet-like note of wrathful denial from Péan, while his adversary still held the floor. Its significance made it of no import that he had already exhausted his right to respond. The denial was thoroughly before the jury.

This, with a few similarly interesting episodes, lightened the tedium of the polyglot monotony. A president of one tongue would sometimes preside entertainingly, yet disastrously, at the reading of a paper in another. One gentleman, turning to illustrate a point on the blackboard, found himself stranded with his drawings and his successor well into a new subject, because the president had fancied his paper concluded. Orators with individual communications on subjects other than the leading ones before the congress were shown to a room apart, where they might read their papers, to themselves at least, in default of better audience.

But these trifles, occasioning hardly a ripple of feeling, served only to accent the cordiality of the banquet board and to demonstrate that in the social comings and goings rather than in the amphitheatre was to be found the worker's heartiest recognition. For here each great man button-holed each other great man, and compared grandeur. Consequently, it was man to man—Frenchman to German, Russian to Italian, American to Spaniard, though oft in pigeon tongue—that the real discussions of the congress were held. It

was this near touch which will enable men to judge of the reliability of the views and statistics of all these familiar names and now familiar faces, when the edited transactions come to be perused in the quiet of the home library. It was this personal contact which allowed the scanning of the statistic makers for truth and conscience and absence of vainglory—for the zeal for science more than zeal for self.

The best men should have the shortest lists and the worst statistics. A zero mortality is easy to a conscienceless man bent on personal éclat. A large mortality is necessary to the conservative man who operates only on desperate cases, and whose ambition is to see how few instead of how many of the women coming before him he can put to the knife. This is why statistics lie. This is why personal knowledge of the operator interprets his figures.

Whether or not great addition to the scientific store has been made, the congress from this social point of view was pre-eminently successful. It showed the arena to the gladiators: man measured man; and from this atmosphere of the leaders in the science of gynecology and obstetrics, one must return to the local clientèle stimulated to renewed labor, taught the vast difference between mere well-fed local success and the honor of contributing even a mite to a world's science.

And humanity profits, although all of the gray heads of the second may not be present at the third international congress.

EUGENE COLEMAN SAVIDGE, M.D.

PARIS, September 10, 1896.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 26, 1896:

	Cases.	Deaths.
Tuberculosis.....	170	114
Typhoid fever.....	25	10
Scarlet fever.....	33	3
Cerebro-spinal meningitis.....	3	3
Measles.....	34	0
Diphtheria.....	127	20
Leprosy.....	1	0

According to the Text-Books.—A bright young "dresser," whose knowledge of anatomical illustrations seems to have exceeded his acquaintance with the operating-table, was asked the other day how he could distinguish between a vein and an artery in an operation. "By the color," quickly responded the youth. "What is the difference?" asked the surgeon. "The veins are a beautiful blue, and the ——" but the remainder of his interesting statement could not be made out owing to the altered condition of the class.—*Medical Press.*

Tobacco.—Tobacco, one of the curses of the world, as pronounced in its malignant influence as dirt; not so hoary-headed with age as filth, but considered more respectable; only the proverbial peck of dirt, the amount allotted to each individual, but no limit placed on the amount of tobacco used; the average chewer consuming nine hundred pounds of the weed, causing an expectoration of about forty-five barrels of saliva; the average smoker consuming seventy-three thousand cigars; the smoke ascending from the cigars and pipes of the world ravalling the fumes of the bottomless pit.—H. M. OCHILTREE, M.D., *Kansas Medical Journal.*

¹An obvious misprint in my letter on this subject in the MEDICAL RECORD, August 5th, may be corrected. The annual sum was printed £2.6s to £3.6s instead of 2s. 6d. to 3s. 6d. It is a case of pence, not pounds—dimes, not dollars.

PRACTICAL POINTS REGARDING THE SENILE INSANITIES, WITH SPECIAL REFERENCE TO PROPHYLAXIS AND MANAGEMENT.

BY RALPH LYMAN PARSONS, A.M., M.D.

NEW YORK.

OF all the mental aberrations and degeneracies, none are more worthy of the attention and study of the general practitioner of medicine than those which occur at advanced periods of life; for while under normal conditions the mental powers should outlast the physical, remaining unimpaired in their essential qualities until the end, it is nevertheless true that in many of the aged the mental faculties fail with or before the physical; and, furthermore, that many of these failures might have been prevented, or at least delayed, if wise counsels had been obtained and followed; and that no one can be so well fitted to give such counsel and advice as the family physician, who is in a position to see and duly estimate the causes which are leading to these failures. And when, in due time, the family physician shall be habitually retained as an adviser of the family in health as well as in disease, as he should be, and as lawyers are now often employed to look after the interests of the family property when it is neither in litigation nor in danger, the physician can render still greater service in warding off the mental diseases to which the aged are exposed. Another reason why this subject deserves the especial attention of the family physician is that the aged are more disturbed by removal from customary habits and surroundings than younger persons, and a proper and laudable respect for their age and for the services of a lifetime demands that their feelings in this regard should be respected in so far as is compatible with their best interests; and so that they should remain longer under the care of the family physician than would be advisable or desirable in the case of younger persons.

We are quite accustomed to expect that mental deterioration will take place *pari passu* with the physical weaknesses that are inevitable at an advanced age. And yet we not unfrequently meet with aged persons who are on the verge of physical dissolution, but whose mental faculties remain unimpaired in quality, and as active as at any other period of life when the body is in a like state of debility from any cause. In fact, the normal brain which is free from disease, in a well-constituted body, ought to be the very last of the organs to fail in its functions. And mental force often proves itself to be the conservator of the physical forces. In proof of this, it is sufficient to note the fact that people who are apparently hopelessly ill and who are told that their recovery is beyond hope, sometimes stubbornly dissent from that view and actually do recover; and when there can be no more doubt that they would have died but for their mental resistance, than we can doubt that of two drowning men of equal physical powers one may save himself by his deter-

mination to do so, while the other is lost by his lack of mental force. And this mental force or its lack does not depend entirely on the original quality of the brain substance itself, but in part, at least, on the sort of training to which the mental powers have been subjected. If these well-constituted brains are less active in later than in earlier years, this can be readily accounted for by the fact that bodily weaknesses hinder and prevent prolonged activity; and also that former incentives to activity no longer exist. It is generally admitted that persons of advanced age are often of better judgment than the young. Nor is it correct to assume that every failure of the memory is an evidence of failure of the mental powers. There are different sorts of memory, and some of these may fail while others persist; those which persist being the ones in which the person takes the greatest interest, or which have been oftenest repeated. And then, with increased years, the number of things to be remembered also increases, and the impressions which have been the fewest in number will naturally be the first to fail in the memory. The impressions of earlier life excited great interest from their comparative fewness in the past, or they have had many repetitions and so have induced a cell habit favoring a reproduction of the impression. Proper names—that is, specific words which are applied each to one specific person or thing—are the soonest forgotten of words, for the simple reason that they are specific, and so of infrequent application. It is only an exaggerated or an essential loss of memory in the aged which should be considered as involving the integrity of the mental faculties; as when the names of near relatives are forgotten, or when the conventionalities of daily life are no longer remembered. And it is even possible for the reasoning powers to subsist with the ability to perform the ordinary duties of daily life, when there is an entire lack of ability to construct a single intelligible sentence or to recall the names of intimate friends.

But it must be acknowledged that with the accession of the physical infirmities and changes incident to old age—the loss of muscular strength, the loss in weight, the wrinkling of the skin, the arcus senilis, the trembling of the hands, the emaciation, the failing appetite, the impairment of digestion and nutrition, the weakening of the action of the heart, the diminished tone and resiliency of the vascular system, attended oftentimes by organic changes of the vessels; the dulling of the special senses, especially of the hearing; the disturbed sleep at night, or the hebetude by day—that these, existing in varying degrees, are often attended or soon followed by important changes in the mental processes—changes which, although they cannot yet be fairly considered as pathological in character, are still an evidence of a weakness that forebodes impending danger. As examples of these mental changes may be mentioned irritability of temper, imperiousness, disturbance of the emotions without sufficient cause, or an undue diminution of emotional excitability, extreme loss of memory, great diminution of the power of attention, diminished power of abstract thought, fickleness, or perversity of disposition.

When many of these signs and symptoms are manifested in a marked degree, the border line of unmistakable mental alienation cannot be far distant. But it should not be inferred that the border line must of necessity be passed. Under wise advice and suitable conditions, the crisis may never be reached; and the reason may be conserved, without essential impairment, until the end. Nor should it be inferred that because the border line has unmistakably been passed, a recovery is impossible on account of the advanced age of the patient; for, in fact, the aged are nearly or quite as likely to recover from an acute attack of insanity as those persons who suffer an attack at other periods of life, when the ratio of persons living at this period is taken into consideration.

And at this point it is well to note that senility is not altogether a matter of years. Some persons are physically and mentally as old at fifty as others are who are ninety or even a hundred years of age. Some families have greater vitality than others; and so their members are likely to live a greater number of years and to become senile later in life. The age to which any individual can possibly survive under the most favorable conditions depends upon the amount of vitality he has inherited from his ancestors. This amount can never be increased, although it may be and often is diminished. And herein lies the indication for means to delay the approach of premature senility and decay, whether on the physical or on the mental side—the removal of influences which are prejudicial and the substitution of those which are advantageous.

The acute mania of the aged differs so little from the acute mania of earlier years as to require only a passing notice, save that the physical resistance to prolonged excitement and loss of sleep is sometimes marvellous. Complete recoveries are not infrequent; and these may be enduring or may give way to subsequent attacks. The maniacal attack is often preceded by a period of mental depression.

The cases of mild maniacal exaltation that are sometimes observed in the aged usually have their origin at an earlier period of life, and cannot be considered as characteristic of senile insanity.

Melancholia in the aged is more insidious in its onset, and may be either a simple mental depression, melancholia without delusions; or it may be characterized by insane delusions. In either form suicidal impulses are common. The simple form of the disease is of frequent occurrence, and recoveries are also frequent. It should be noted, however, that such false ideas, as that some great calamity is impending, that they are becoming impoverished, that they have ruined their friends, that their souls are lost, or that they have committed the unpardonable sin, should not be ranked as essentially insane delusions—that is, as delusions which are in themselves diagnostic evidences of insanity. The essential characteristic of this form of insanity is the emotional depression. The gloomy ideas are the direct outcome and result of the depressed emotions, and not their cause.

In the delusional form of melancholia, in the aged no less than in earlier life, the delusions are of an essential character, as that their most devoted friends have become their malignant enemies, that their food is being systematically poisoned, that they are to suffer a violent death, or that their bowels are inhabited by snakes. Incredible delusions of this sort are indicative of a profound mental degeneration, and recovery is very much more rare than in the simple form.

If recovery from these acute forms of senile insanity takes place, subsequent attacks are liable to follow, especially if care be not taken to avoid the exciting causes. The same predisposition which was the basis for the first attack must still persist, and in a

brain already weakened by the previous attack. If recovery does not take place, the patient usually passes into a condition of consecutive dementia, from which recovery is not to be expected.

The typical insanity of the aged is a primary dementia, which differs from the primary dementia of earlier life in that it is incurable; depending, as it does, on organic changes in the tissue of the brain. Primary senile dementia is in many particulars similar to general paresis, its characteristic condition being one of weakness.

Oftentimes this form of senile insanity is very insidious in its onset. In the earlier stages it may be very difficult to distinguish the approaches of a dementia which leads inevitably to a condition of fatuity, from the mere lack of mental activity which accompanies the physical infirmities of the aged while the reason still remains unimpaired. In this stage of the disease the demented person often performs acts which are foolish in the extreme, and which may lead to serious medico-legal complications. He becomes penurious, depriving himself of the comforts and necessities of life, or he disposes of his property without reason or consideration; he makes unwise marriage engagements, or makes improper proposals to women, or, more likely, he makes indecent assaults on little girls. The sexual instinct often persists in the aged dement when the power has become nearly or quite extinct.

Later on, both body and mind inevitably fail in strength, especially the mental powers. The dement then wanders aimlessly about, meddling with whatever comes within his reach, or he busies himself with placing and replacing articles without value. He loses all ideas of the conventionalities of life, of decency, of persons, and of places; he removes his clothing, urinates in a corner of the room, or he passes his excrements unconsciously; or he becomes utterly stupid and apathetic, with, perhaps, alternations of excitability and depression. And from this condition there is no reprieve until the end.

The causes of the senile insanities, some of which are coincident with the causes of the other insanities, may be conveniently considered under three categories—those which are so remote as always to have been practically beyond our control; those which are in action at the earlier periods of life; and those which are in action when senility is already impending.

There can be no question that heredity and congenital influences are important factors in determining the mental status in any period of life. If these influences are beyond our control, their consideration may be an important aid in making our prognosis and in advising such measures of prophylaxis as may be required.

The second class of causes is also worthy of consideration, not only with reference to prognosis, but also because, although somewhat remote, they may still be controlled or modified if only timely advice be given and heeded; and it is at least barely possible that here and there a person may be found who will profit by advice bearing on the yet remote future. These causes are, for the most part, such as tend to produce organic changes in the vessels of the brain or to bring about a state of exhaustion of the physical or mental powers—as chronic alcoholism, syphilis, gout, rheumatism, venereal excesses, great and prolonged physical strain, intense and long continued mental application, with anxiety or worry; and lack of self-control, as indulgence in the passions of grief or of anger. A mere mention of these causes is enough to suggest the measures of prevention that may be required. On the other hand, a life of self-control and moderation in all things is the best possible safeguard against a premature breakdown in advanced life.

The causes, however, which are in operation when at a somewhat advanced period of life the infirmities of age begin to make themselves felt are of more immediate importance; because the advice of the physician is then more likely to be sought and followed. Some of these causes are the same as those pertaining to an earlier period of life, and are only of more importance now because the power of resistance has been diminished. Others are especially pertinent to the advanced period of life. It will be a matter of convenience to consider measures of prophylaxis in connection with each, in turn.

When the physical powers begin somewhat to fail, with advancing years, giving notice of the greater disabilities that are soon to follow, there is oftentimes a great disinclination to heed the warnings thus received; a tendency to engage in exhausting labors in competition with those who are still in the prime of life, and to encounter hardships and exposures which might have been borne with impunity in earlier years, but which now involve a strain which is likely to prove injurious in its results. There seems to be a sort of pride in appearing not to have lost anything of pristine vigor. Although it may be evident enough to others that a moderate pace should now be taken, advice to this end will usually be required.

But the opposite extreme should also be avoided. The entire giving up of accustomed physical activities may be even worse than their continuance. It is often observed that those who suddenly and entirely cease from their accustomed work fail more rapidly than do those who continue their labors, only there should be a diminution in the amount and hours of physical activity, in due accord with the bodily failing and disabilities.

Although mental work with a well-constituted brain may usually be continued more fully and later in life than physical work, this should also be diminished with advancing years; both because the brain then requires more rest and more time for recuperation, and also because severe mental work is of itself exhaustive of the bodily powers. But here, also, an entire giving up of mental work may be more injurious than its full continuance. What is required is a continuance of mental activity with such changes in amount and quality as are in accord with its diminished powers of endurance. And these changes in habit, both mental and physical, should be made not after this has become compulsory through loss of ability, but when the first intimations of the coming necessity begin to make themselves observed and felt.

Among the premonitory symptoms and the immediate causes of insanity in persons who are becoming old, lack of proper and sufficient food and lack of sufficient sleep are prominent. With advancing years, a certain degree of insomnia comes on, the nights are restless, and so the sufferers from insomnia remain sitting up or wandering about, because they thus seem to be less uncomfortable than when tossing about in bed with inability to sleep. When they finally lie down and fall asleep, their sleep is disturbed and unrefreshing, and they awaken with or before the early dawn, having secured only a moiety of the sleep they really require; or, after an almost restless night, they fall asleep after daybreak, when others are just beginning the occupations of the day. And thus the vicious circle is commenced of turning night into day and day into night, with all its inconveniences and drawbacks; for the nighttime, with its quietness and freedom from causes of disturbance, is a much more favorable time for normal, restful sleep than the daytime, with its many causes of disturbance. And yet, if sleep will not come at night and does come by day, this is certainly better than no sleep at all. But every possible means should be employed to break the

vicious cycle and to secure a sufficient amount of restful sleep during the hours of night. It will often be found that a short nap taken once or twice during the day will favor better sleep at night, by relieving the nervous irritability which tends to prevent sleep.

And then there are many things that the aged sufferer from insomnia may do to promote sleep. A warm bath taken just before retiring, with cold applied to the head, may be an efficient aid. A cold douche to the feet and legs, or a wet pack to the abdomen, is sometimes useful. A light supper just before retiring is usually of advantage.

Babies and brute animals are usually somnolent when their stomachs are well supplied with food, the activity of the stomach withdrawing the excess of blood from the brain, where it is not needed during sleep. On the other hand, people who are very hungry usually find it difficult to sleep. And, then, a habit of sleep at a regular time and during proper hours should be cultivated in case this habit has been lost. In accomplishing this, the attainment of a favorable state of mind is of great importance. Sleep cannot be enforced by a direct exercise of the will. The very effort of the will to command sleep is enough to render its attainment nugatory. The mental state to be encouraged is one of quiescence, one of indifference, a feeling that the recumbent posture is a proper one for rest, and that if the thoughts are disposed to continue active they may be safely allowed to take their course without any effort toward control. This state of mind and thought is next akin to dreams, and dreaming is next akin to sound sleep. Many mental methods have been advised and put in practice for the purpose of securing sleep, the design being to turn the thoughts from objects of interest to a condition of monotony; as by mentally repeating well-remembered phrases or sentences, or by counting. But the state of indifference, if this can be obtained, is likely to be the most efficient, as being the least active. The mere mention of these simple methods will be sufficient to suggest others equally effective.

Equally important with restful sleep is the taking of a sufficient amount of nutritious and easily digestible food at proper intervals; for one of the usual forerunners of a mental breakdown is loss of appetite or neglect in the taking of food. Not that the stomach should be overburdened with food, for this, too, would be prejudicial; but that a sufficient amount of suitable food for the purposes of nutrition should be taken at proper intervals. If the nights are restless, a glass of milk and a biscuit may often be taken with advantage on awaking in the middle of the night or toward morning; or a glass of warm milk in the early morning before rising.

In case an actual attack of insanity should supervene, one of the first questions to arise will probably be whether the patient can be better treated and managed at home and among his own friends or away from home. The conditions and circumstances vary so greatly in different cases that each one must practically be considered by itself. In a general way it may be said, however, that the acute cases usually do better under skilled treatment away from their homes and their intimate acquaintances. And since these patients have a fair prospect of recovery, they should be given every advantage that tends to secure this desirable result and without too much regard to their feelings or wishes in the matter. If it is decided, however, to treat them at home, their domicile should be made a private hospital, in so far as may be required for their successful treatment, or until all reasonable expectation of recovery has passed away. Especial attention should be given that they get sufficient food and sufficient sleep; and inasmuch as the melancholics almost always have suicidal propensities,

these should always be under efficient supervision. In case food is persistently refused, resort should be had to forcible feeding; and there should be no unnecessary delay in doing this, for the longer the delay the more obstinate is the refusal likely to be, while with delay the physical powers are liable to become too much impaired to admit of recuperation. But, before resort is had to forcible feeding by means of the œsophageal or the nasal tube, every possible means should be employed to induce the patient to take food with something of volition, by persistent and strong persuasion, or by an assurance that force will certainly be used if required. If forced alimentation be required, the œsophageal tube has the advantage of being safer and of admitting the use of more solid food, an advantage in itself if the feeding is to be long continued. In addition to the means already mentioned for securing sleep, drug treatment may now be advisable; the various well-known hypnotics being employed in turn, in order to avoid the danger of establishing a tolerance for any one of them and thus limiting the means of relief at our disposal. Another reason for a frequent change in the hypnotic drugs administered is that, inasmuch as all potent remedies have their disadvantages, each in some particular way, as well as their advantages for the specific need, the disadvantageous action of the remedies will be distributed and thus reduced to a minimum. Opium is rarely to be recommended as a hypnotic. It may be of use, however, in very small doses, as a stimulant in cases of melancholia.

The wet pack is also sometimes useful, acting as a revulsive from the head, relieving the dryness of the skin and at the same time securing a state of bodily quiescence which is favorable to sleep. The application of some form of the electric current, or suitable massage may also be of advantage. Those little monotonous attentions which are well known to be so soothing in the care of restless children should not be forgotten. The mere presence of the nurse as a bedfellow, with a hand resting on the person of the patient, may afford a sense of security or relieve a sense of lonesomeness, and so promote sleep.

It is always to be understood, as a matter of course, that all concurrent and intercurrent diseases will be treated in accordance with the requirements of each.

The decision of the question whether the subject of senile dementia should be treated at home depends chiefly upon two considerations: First, whether this can be done without too seriously compromising the welfare of other members of the family; and secondly, whether, all things considered, the patient can be made as comfortable and as happy as at some available place elsewhere. But, there may be no suitable home; there may be neither relatives nor friends who are willing and competent to undertake the necessary supervision and care; for, however kind and willing the friends of the patient may be, the task may involve too great a strain upon their sympathies and on their powers of endurance. Or, as often happens, the patient may be less tolerant of the necessary measures of care and restraint at the hands of relatives than at the hands of others. All these considerations should be carefully taken into account by the physician who is called upon to advise. If, however, these two questions can be answered in the affirmative, inasmuch as a cure is no longer to be expected, there can be no doubt that such of these patients as have a home and devoted friends ought not to be removed elsewhere for care and treatment.

It often happens that the relatives of the aged dement are quite competent to give all the care and nursing that may be needed. If not, suitable nurses should be employed; and, even for the care of men, female nurses are to be preferred, if competent for the per-

formance of the required duties. Or if, as sometimes happens, kind-hearted neighbors volunteer their services as nurses, these untrained volunteers, as well as the family of the patient, need to be especially instructed regarding the nature of the service to be done. A neglect of this precaution has sometimes led to disastrous results, from a failure in the proper observance of sanitary measures, when the patient has become bedridden and can no longer control his evacuations. And so instruction will usually be needed in regard to the proper ventilation and cleanliness of the apartment occupied by the patient; the removal of carpets, curtains, and upholstered furniture; the immediate removal of all evacuations and other sorts of filth; scrupulous cleanliness of the person; the prevention of bedsores, and so on. In other respects, no special experience is required for the proper management of this class of patients.

APPENDICITIS—TO OPERATE OR NOT TO OPERATE.¹

BY JAMES H. DUNN, M.D.,

MINNEAPOLIS, MINN.,

PROFESSOR OF GENITO-URINARY AND ADJUNCT PROFESSOR OF CLINICAL SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF MINNESOTA.

DESPITE the trite maxims that doctors are prone to disagree, and that many men incline to many minds, no one, whether layman or practitioner, can fail to be astounded at the wide and positive divergence of the opinions which have prevailed and still do prevail as to the proper management of the condition termed appendicitis.

One may readily recall numerous medical and surgical topics upon the details of which authorities have been in far from complete accord, but it is perfectly safe to say that during our generation at least no equally clear and definite condition has been faced by two partisan and nearly diametrically opposite camps of advisors, who have often met the views of each other with almost brutal bluntness if not with apparent contempt. Candor compels me to admit that the assertions of both medical and surgical partisans appear more ardent than accurate and that one often meets with cases which exhibit the sad results of an absurd partisan teaching and preaching of abstract nonsense rather than modest scientific study of the cases in hand. On the one hand are cases "cured" into irreparable intestinal adhesions and complications by the scouts of surgical treatment, and on the other hand precipitated into the hereafter by indiscreet, incipient disciples of the shouters of "always operate."

I have said one is at first glance amazed at the diametrically opposed views so generally set forth on what might appear to be, as medical problems go, a relatively simple and now fairly understood condition, but further scrutiny shows this problem, like most great pathologic and therapeutic equations, far from as simple as the disputants seem to indicate. To label a train of pathologic events as variable as those comprised in appendicitis with a name and to place opposite it a specific treatment or operation is but to incite the hordes of comparative ignorance, inexperience, and impracticability to pernicious activity rather than to invite candid, patient study of phenomena and sensible adaptation of remedies to specific conditions and surroundings.

You may have listened, as I have, to medical extremists who report scores, even a hundred consecutive cases of appendicitis cured without operation and

¹ A paper read before the Mississippi Valley Medical Association, September 18, 1896.

without a death. To most of us this would appear a very rash statement, even on first thought—one calculated to impair our confidence in the veracity or judgment of the reporter. Yet nothing is easier to understand. These good people only mean to say that all those cases which they have recognized as appendicitis have appeared to recover. To such I would reply, we surgeons may learn one thing from you, namely: that an astonishing percentage of these cases, and even most threatening ones, recovers more or less completely from the acute attack. But you have two lessons to learn from us; first, you clearly fail to recognize a small percentage of appendicitis cases, namely: those fulminant cases of peritonitis, the appendical origin of which is well known to surgeons experienced in abdominal work. Second, if you carefully follow your patients long enough you will find that a large proportion of them are far from being cured; indeed, some die suddenly after being cured from one to half a dozen times; while others become invalids from a great variety of obscure ailments due to intestinal adhesions and other sequels of the natural cure, which are sometimes difficult, if not impossible, of subsequent relief.

After a considerable experience with the disease treated without operation as well as on the operating and post-mortem table, I must admit that the clearly overdrawn assertions of these medical extremists astonish me less than those of some of our prominent surgical teachers. I say this, because the surgeons by their opportunities of direct observation ought to be, and in general are, more practically familiar with the whole course of this disease than are medical clinicians.

Turning to the latest surgical monograph at hand, "A Treatise on Appendicitis," Deaver, 1896, I find, page 113, "It is true some cases will eventually recover by medical treatment (sixteen to four hundred according to Ribberts) and a slightly greater number will apparently recover from an attack."

Now, so long as we advise upon such absurdly extreme views as these, we must appear to give each other the lie direct, and as between the medical and surgical enthusiast the patient must take his choice, while the comic daily editor does the rest. As already remarked, the views of the surgical extremists are on the whole the most enlightened, and, hence the greater harm of their often absurdly overdrawn and rashly stated dogma.

If the line of a surgeon's personal experience leads him so overwhelmingly into surgical cases as to justify such a doctrine as just quoted, the very positive observations of the medical brethren, although doubtless and even clearly containing elements of error, should receive sufficient respect to admonish more caution and less dogmatic teaching. Just so long as a surgeon of eminence holds as a fair statement of the non-operative treatment that but sixteen out of four hundred cases may be expected to recover permanently, and, more especially, that but a slightly greater number will recover from one attack, just so long may we expect every sound-headed general practitioner to scout, or at least heavily discount, the opinion of surgeons, because his personal experience leads him to know better with absolute certainty, and, having found surgical teaching clearly false in this particular, naturally to turn his ear from other facts which surgical experience could furnish him and of which he ought to be cognizant in giving wise advice to his patient. So long as surgeons say to these men, What you observe to be white is perfectly black, there is no ground for assimilating facts or for advancement of practice.

If this line of treating the subject drives the experienced general practitioner to a dangerous and obstinate suspicion of surgical treatment, it leaves the young and inexperienced practitioner, of late with a much overgrown and rather unhealthy surgical ten-

dency, to face the overdrawn dangers of appendicitis with ill-timed, ill-placed, or ill-executed operations which may easily prove yet more dangerous. My own experience leads me to know that one great class of practitioners greatly underestimates the dangers of appendicitis, while another, becoming almost as numerous, as greatly overestimates it.

Another class of surgeons has tried to quash the whole discussion of the treatment of appendicitis by a simple application of logic, thus: Some cases of appendicitis can only be saved by early operation. No one may infallibly distinguish these cases from those which may recover without surgical interference. Ergo, always operate at once; the diagnosis is made. Logically, and on paper or in discussion, I find this position fairly good. The rule is certainly easy and simple and removes a multitude of difficulties from the practitioner, but I fear only transfers them to the patient. In all practical matters of this life one finds none so fallible as those who strive after and adopt infallible rules of action. Such individuals err about as frequently as less positive mortals, and when they do go astray their blunders are often those of genius, such as a modest fool could not commit. In practice such a simple rule finds many and serious objections. Time forbids a discussion of the proposition directly and I shall seek a shorter refutation in the general axiom that any treatment which takes nothing into account but a single disease factor, giving no heed to the patient himself, his circumstances and surroundings, is on its face unworthy of the consideration of practical scientific men. Circumstances alter cases. True, if we try each case on its own merits and strive to operate when, where, and in such manner as the indications and the circumstances interpreted by keen observation and toiling skill seem to dictate to be for the individual's welfare, we shall sometimes fail to have done the best thing at the right time. But will the advocates of "always operate" at once prove any nearer infallible? When they shall have proven so and have been able to say: "Do as I bid and I can assure you of recovery," then I shall yield. But till then I prefer to seek indications—now operate at once, now delay; or again not operate at all. Time forbids boring you with statistics, and besides they are, as mostly used, the tools of error quite as often as of truth. Suffice it to say that during the past six years I have had to do with more than one hundred and fifty cases of appendicitis and have operated myself upon about fifty cases. Of those not subjected to operation many have passed out of sight, but a good number have been kept track of from one to five years. From such observations as I have been able to make, I conclude:

First, that a small percentage of cases of appendicitis, possibly between five and ten per cent. of acute attacks, is absolutely fatal unless promptly relieved by surgery. Here to be very successful the interference must usually be undertaken very early, generally within forty-eight hours of the onset, or at least of the onset of the threatening symptoms. The condition is so dangerous that surroundings and imperfect operative advantages need not have the influence they must claim in subjecting a patient in less peril to a preventive operation. While it is perfectly true that it is difficult always to recognize the sudden perforative form, a good and careful clinician may by study of the onset and the course of the disease during the first few hours distinguish these cases as accurately as most other internal diseases. The operative technique places the least demands upon the operator and the peril of the patient justifies the less perfect operative installation of an emergency operation.

Second, in the other ninety or ninety-five per cent. of cases the emergency is not so great. However, the patient is in the clutches of a treacherous disease and

it is always well to mount the guard and prepare for action. If conditions are in every way the most favorable—the best of surgical attendance, the best of hospital advantages—and the patient upon a just and fair statement of the facts consents, I believe appendectomy is the most certain and complete course. On the contrary, if operative conditions be not very perfect, to rush upon such a patient an operation will not much improve the general mortality rate and quite certainly sometimes lessens the individual chances. I have many times refused to operate because the patient was in a most critical state, such that with the surrounding conditions one would rather trust to the *vis medicatrix nature* than to surgery, and I have been surprised to find that patients sometimes recover entirely, and at other times reach a more favorable stage for successful operation.

Third, when as a consultant, or otherwise, one is called in to a case after the fourth day and up to the tenth or fifteenth, when the symptoms indicate a localization of the trouble I am particularly inclined to conservatism, and in this stage, I think, one should never "always operate," but should always hesitate and feel the way unless there are pretty clear indications for interference. A case having progressed to the fourth day favorably, *i.e.*, without alarming symptoms and with evidences of strict localization, we may be unable to predict the final outcome, but the chances are less than one in ten that the patient will fall into a sudden danger. An abscess may later need to be opened, but a very large majority will, at least temporarily, recover or reach a stage where a safer and better operation may be performed. The periods of election for appendectomy are very early or very late, or between attacks. The direct dangers are less at these periods and completer operations may be made with better closure of the abdominal walls.

Fourth, again in this intermediate stage, great care and judgment are necessary in the operation in order to do just the best thing. As a rule, with some exceptions, the operation should consist simply in opening and draining without attempt to remove the appendix or without breaking down protective adhesions. Here experience and skill in operating and in the after-management are very necessary to the best results; for, while nothing can be simpler than to open and drain many of these abscesses, in others to do a little too much, or a trifle too little, will sacrifice the case. In one we open the pointing abscess with a stroke or two of the knife; in another we explore with the utmost care, find an extra-peritoneal opening which will really drain the irregular, variously located, perhaps multilocular collection, and in others it will be best after this to remove the appendix. For the most part, however, these are incomplete operations and it may or may not be necessary to subsequently remove the appendix, or repair a hernia, or both.

Many of the milder cases of appendicitis appear to reach their acme by the third or fourth day and gradually to subside during the following week. But it is not rare for others to show little general improvement before the end of eight or ten days and yet recover very completely.

Fifth. But as a rule, if at the end of ten or twelve days there is not some progressive abatement of the disease, I think we may assume that an abscess exists which it is in general useless as well as dangerous to leave to nature and which should be opened without entering the general cavity.

Sixth. In all relapses, certainly after the second, it is good advice to operate either after the attack has subsided or on the first symptom of the relapse. It is well known that these cases form the most favorable class for operative interference: first, as regards the mortality, which ought not to be above two or three

per cent., and second, because the operations may be completed as a rule without drainage and with the most perfect closure of the abdominal walls. Next to operations during the early hours of preliminary acute attacks, those between the attacks are the simplest and most definite in technique. Often an operator with good theoretical training and little experience in abdominal surgery will find such cases easy, but occasionally they present complications in the way of intestinal adhesions, sequestered appendix, etc., which renders the experienced surgeon an easy victor where the novice would fail or expose the patient to entirely unnecessary dangers.

Thus, I do not find the indications for operation in appendicitis or not to operate in a fixed rule based upon logic, upon the day of the disease, the temperature range, or any other single rule of thumb; but upon broad clinical principles, aiming to estimate as closely as possible the conditions present and to meet them by such means as the variety and stage of the disease, the condition of the patient and his circumstances may seem to demand. By such a course it is not possible to avoid occasional errors of operating too early as well as too late, of doing too much as well as too little. But I feel sure a good clinician, guided by a wide knowledge of the pathologic and the clinical course of the affection, will be able to feel his way with as few mistakes as the positivist who acts upon an absurd rule, however laconic, whether that of "always operate" or "never operate."

I am able to say that of about one hundred cases not subjected to operation, the direct mortality was less than ten per cent. A considerable number appear to have made complete recoveries, lasting from a few months to five years. Very many are known to have had relapses; some have been soon lost to view. My impression is that scarcely half have remained perfectly well. In fifty-two cases selected for operation upon the lines here laid down there were four deaths. In thirty-eight the appendix was removed and in fourteen it was not. Some years a score of cases have been seen without meeting one submitted to operation. Again, for some months most of the cases have appeared to demand operative interference; at one time a number of relapsing or chronic cases present; again, a dozen or more consecutive acute suppurative ones. Of the fourteen incomplete operations, six have occurred consecutively in the past few months; indeed, four of them in one month. Hence, in my experience, appendicitis is not a condition to be dogmatically treated of by a few sweeping assertions, but one presenting a very varying aspect, to adequately meet which broad judgment, broad clinical knowledge, and experience are necessary. On the whole, it is far more a surgical than a medical disease. I have more quarrel with the prognosis of the surgical extremists than with their treatment, for, though my experience leads me to know that the probable mortality of an attack of appendicitis is not, in considering a large number of cases, very greatly above ten or fifteen per cent., the probabilities of cure are quite otherwise, and I have no doubt whatever that at least the minority ought soon or late to be subjected to surgical treatment.

This absurdly false prognosis leads to great misunderstanding and inopportune interference. On the other hand, the quite as inaccurate claims of medical extremists, that because a patient gets up from an acute attack he should be regarded as a cure, a living reproof to surgeons, and a dazzling medical trophy, leads to quite as disastrous sins of omission. I would have the medical brethren look for some of the medical cases which are a shame rather than a glory to medicine and admonish surgical extremists that insisting upon an absurdly grave prognosis retards rather than advances sound practice.

PREGNANCY COMPLICATING OPERATIONS ON THE UTERUS AND ITS APPENDAGES.¹

BY R. STANSBURY SUTTON, M.D., LL.D.,

PITTSBURG, PA.

On March 30, 1891, Dr. Bell, of Butler, Pa., brought to my private hospital Mrs. S—, aged twenty-six years. She was three and a half months advanced in her sixth pregnancy, five of which had terminated in three living children and two miscarriages. After the cessation of each of these periods of utero-gestation, a tumor could be felt to the left of the uterus. Upon examination, a well-defined cyst was distinguishable, occupying the abdominal cavity. Below and to the right side of it the pregnant uterus was located. Upon opening the abdominal cavity, I encountered a large cyst of the broad ligament on the left side. Its contents were evacuated and the cyst was enucleated.

After the enucleation, which was tedious and difficult, there was tolerably free bleeding. The cavity was irrigated with hot water, and the wound was closed with two rows of buried catgut sutures and a superficial row of interrupted silkworm-gut sutures. She was discharged twenty-three days after the operation. Her pregnancy went on without interruption, and she was confined at term, her child living.

Notwithstanding that this patient had aborted in two subsequent pregnancies, the operation failed to provoke any trouble in this, her sixth pregnancy.

On February 13, 1893, Mrs. D—, aged thirty-four, widow for ten years, mother of one child, thirteen years old, was sent to me by Dr. Beatty, of Alleghany, Pa., for operation. At her menstrual periods she had cataleptic seizures, and frequent attacks of severe pain in the ovarian regions. She was incapacitated for work, and protracted treatment and all remedies applied had failed to relieve her. She stated that her last menstruation had occurred two weeks prior to this date. A digital vaginal examination revealed a linear contraction at the juncture of the upper and middle third of the vagina, which arrested the finger. The finger was now transferred to the rectum, and by the aid of the superimposed hand I made the following diagnosis: Lacerated cervix, subinvolution of the uterus, chronic salpingitis and ovaritis.

Five days later I made a very short incision in the median line, and through it removed the ovaries and tubes. I noted the supposed subinvolution of the uterus with the fingers, and closed the wound. The patient recovered promptly, and left the hospital. About ten months after her discharge from the hospital, her attending physician informed me that in nine months less forty-one days after the operation, he had attended her in confinement. She gave birth to twins, healthy children.

Occasionally an ectopic and a uterine pregnancy coexist. The great majority of such cases have, in the past, ended fatally. In the future, the question of doing abdominal section or an operation for tubal gestation is much simplified, in this fact, at least, that the coincident uterine gestation is not a complication worth serious consideration, and hereafter a diagnosis in any case of tubal disease or suspected ectopic gestation may be elucidated safely—although uterine pregnancy exist—by an exploratory incision.

The fact that twin pregnancy, one fœtus in the uterus and one in the tube, has occurred many times; that such a condition has usually proven fatal; and, further, since in all recorded cases a correct diagnosis has been arrived at only four or five times, the question of intra-abdominal operation in the presence of uterine pregnancy is swept of its terrors for the future.

¹ Read at the meeting of the Mississippi Valley Medical Society, St. Paul, September 15-18, 1896.

Intra-peritoneal operations made directly on the pregnant uterus, with the expectation that such operations will not disturb the progress of the pregnancy, require a much more critical consideration and greater caution, for not only is the life of the fœtus involved, but the life of the mother may very easily be sacrificed.

In the myomectomies done thus far on the pregnant uterus, nearly sixty per cent. of the mothers have been lost, and enough of the children have been lost to swell the mortality to more than one hundred per cent. Unless, therefore, the tumors have but a slight attachment to the pregnant uterus, myomectomy under such circumstances had best not be done.

In three cases of pregnancy, dangerously complicated by the presence of fibroid tumors in the body of the uterus, I have done supravaginal hysterectomy, by Chrobak's method—in each instance sacrificing the fœtus and saving the mother.

It is a remarkable, and yet a natural consequence, that a uterine myoma is usually stimulated to a very rapid growth by the process of uterine gestation. I say a natural consequence, for what difference is there, histologically, between a pregnant uterus and a myoma? Practically they are identical.

In one of my cases—all of which are published in the Transactions of the American Gynecological Society—the tumor weighed ten pounds. It is a somewhat remarkable fact that in these three cases all the women were primiparæ.

Recently I have seen a fourth case, in which there has been up to this date no surgical interference. This patient is also a primipara, and in the sixth month of gestation. She is so located that she can be temporized with, in the hope of doing a Cæsarean section and thereby saving both the mother and child.

Believing, as I do, that the existence of myoma in the uterus of a woman before marriage is a source of the greatest danger, if marriage is contemplated I hold that the tumor should in every instance be destroyed, either by myomectomy, enucleation, hysterectomy, removal of the ovaries and tubes, or by ligation of the uterine arteries; and also that it is the duty of the medical man to advise against marriage until a cure has been effected.

The Indications for Ventral Fixation of the Uterus.—The following indications for ventral fixation of the uterus are given by Dr. G. M. Edebohls in the *Medical News*: 1. Vaginal fixation of the uterus does not come within the sphere of legitimate operations in women liable to future pregnancy. 2. The indications for ventral fixation of the uterus should be limited to the utmost degree in women liable to subsequent pregnancy. 3. Ventral fixation is never indicated in uncomplicated retroversion of the uterus. 4. Inability of an operator to perform shortening of the round ligaments may be an indication for ventral fixation, but not in the case of one claiming to be a specialist in gynecology. 5. Ventral fixation is indicated, as an adjuvant, in the performance of combined operations for prolapsus uteri et vaginæ. 6. Ventral fixation is indicated as a closing step in all cœliotomies in which the adnexa are removed and the uterus is left. 7. Ventral fixation may be indicated, under exceptional conditions, in cases of adherent retroversion, with tubes and ovaries in good condition. 8. Ventral fixation may be indicated in the most aggravated cases of uncomplicated sharp retroflexion. The writer has not met such a case not amenable to successful treatment by shortening the round ligaments. 9. Ventral fixation is indicated, under certain conditions, in cases of uterus unicornis.

TWO CONTRIBUTIONS TO THE SURGERY OF THE GALL BLADDER.¹

BY J. R. HOLLOWBUSII, M.D.,

ROCK ISLAND, ILL.,

SURGEON TO ST. ANTHONY'S HOSPITAL.

THE rapid development of surgery of the gall bladder and the frequency of operative procedure for the relief of disease of this viscus almost preclude the possibility of anything new being said on this subject. Accuracy and amplification of our knowledge, however, are only obtained by experience; therefore, it is much to be desired that every case bearing upon this subject should be reported, to the end that an analysis of a series of cases may be of benefit to the profession. For this reason the two following cases of gall-bladder disease, that have recently been under my care, are presented to your notice.

CASE I.—Mrs. S—, aged fifty-four years, was brought to me by her family physician, Dr. O. M. Looker, of Hillsdale, Ill. For some four years she has been complaining of pain and tenderness in the region of the stomach and liver. This ever-present soreness was accompanied at intervals by attacks of severe and almost unbearable pain, followed by nausea and vomiting. As time progressed these attacks increased in frequency and severity. Jaundice, which at first was present only after an attack of colic, now became almost constant, and the only rest obtained was that produced by narcotics. When she was first seen by me, her appearance was indicative of great physical sufferings—debilitated and emaciated in the extreme, face pinched and anxious and jaundiced in color—altogether not presenting a condition likely to withstand a severe operation. Upon examination of her abdomen, a large, hard, nodular mass was found occupying the space between the eighth and ninth costal cartilages and the umbilicus, the entire tumor tender and painful to the touch. At the lower portion of this neoplasm was a smaller circumscribed tumor which could be readily outlined from the remainder. This portion was exquisitely tender to the slightest pressure. The previous history of the case, together with the condition found on examination, left the diagnosis between gall stones and malignant trouble of the pylorus, or both. She gladly accepted the proposal of an operation, in hopes of alleviation of her suffering.

December 21, 1895, under ether anaesthesia, an incision in the median line was made and the diseased mass was exposed. The pylorus was found to be the seat of a large carcinoma, and the left lobe of the liver was also infiltrated with carcinomatous nodules. The walls of the gall bladder were diseased, thickened, and friable. The gall stones now could be readily felt, filling the bladder to its utmost capacity. The viscus was incised and twenty stones were removed, some of which are here presented. The incision was closed by a row of interrupted sutures. The friable condition of the walls rendered the coaptation of the serous surfaces very difficult, and some apprehension was felt that leakage would occur; but, happily, no such accident followed. The abdominal wound was closed in the usual manner, and the patient made an uninterrupted recovery from the operation, being discharged from the hospital on the nineteenth day. For some weeks succeeding the operation she was free from pain and more comfortable than she had been for years; but the respite from suffering was cut short, and in a few days over three months she succumbed to the disease.

CASE II.—Mrs. C—, aged forty-six, was referred to me by her family physician, Dr. Eddy, of Milan, Ill. This patient gave a history of six years of inter-

mittent suffering—spasms of hepatic colic, accompanied by temporary icterus, vomiting, and general prostration. These attacks usually confined the patient to bed for from one to three weeks, the soreness and tenderness resulting from the acute pain remaining for some time. The intervals between attacks were generally comfortable, with the exception of more or less indigestion. The increasing frequency of the spasms, their intensity being such as to endanger life from collapse, led her to seek surgical relief from her suffering. When she was first seen by me, her general condition was fair, although she was somewhat weak from her last attack of colic. Upon examination of the abdomen, no circumscribed tumor could be felt, as in the case of Mrs. S—-. Deep pressure, however, revealed an undefined swelling. By passing the tips of the fingers under the free margin of the liver, a hard nodule could be felt. A diagnosis was made of impacted gall stone. Under ether, the median incision was made. As soon as the edges were retracted, the enormously distended gall bladder came into view, in size some five to six inches in length, and of the circumference of a man's wrist. The contents, a mucoid fluid, were drawn off through a cannula, and the bladder was incised. A stone weighing sixty-nine grains was removed. The cystic duct was found impacted with a stone, about the size of a joint of the little finger. Considerable difficulty was experienced in crushing and removing it. The duct was now pervious, but the inflamed and hardened condition of the walls determined the use of the Murphy button in making an anastomosis with the duodenum. This was accordingly done, and the viscera were returned. Considerable bile had escaped, notwithstanding careful gauze packing; therefore the peritoneal cavity was thoroughly flushed with hot water. The abdominal wound was closed with three tiers of stitches and dressed with aseptic dressings. The operation lasted two hours, owing to the difficulty in removing the stone from the duct. The patient bore it well, and made an uneventful recovery. The stone removed is a hexagonal cube, four sides of which have been worn smooth by constant rubbing upon the face of the stone in the duct.

The clinical histories of these two cases are entirely different. The conditions present upon examination were equally dissimilar. They emphasized the diagnostic points already laid down by writers on this subject, and especially those given by Mayo Robson, in his paper on "Surgery of the Gall Bladder," read before the international medical congress in Rome in 1894. He says that in all cases of malignant disease with jaundice the gall bladder formed a perceptible tumor, while in jaundice dependent upon gall stone alone no marked tumor was present. In the first case here reported, the tumor was perceptible to the slightest touch; while in Case II. it was only by deep pressure under the liver that a tumor was recognizable, and that only because of the large size of the stone. The jaundice in the first case was almost constant, while in the second it only followed the acute attack of colic. These two cases illustrate how unjust it is to both the patient and the physician to allow disease of the gall bladder to be treated by medical means alone, until the patient is reduced by years of pain and suffering to such physical condition that surgical relief is only a *dernier ressort*. It is safe to say that the irritation produced by gall stones, either in the bladder or in the ducts, is an important etiological factor in the production of carcinoma of the stomach and liver. When jaundice has become constant and cachexia has developed, we have a class of cases very unfavorable for surgical relief. The danger from collapse in the intense spasms seen in the second case offers sufficient reason for operative procedure in similar cases. Ulceration and perforation of the duct are accidents liable to oc-

¹ Read before the Central District Medical Society of Iowa and Illinois, at Rock Island, Ill., April 9, 1896.

cur when the impaction is so complete as in this case. Erosion of tissue will soon follow the constant pressure here observed. The foregoing cases are not unfamiliar types of gall-bladder disease, and are reported with the hope that in making up the sum total in these operations they may serve some end.

THE TREATMENT OF ACUTE ABSCESES.

By EDWARD W. PEET, M.D.,

NEW YORK CITY,

ASSISTANT GYNECOLOGIST TO ROOSEVELT HOSPITAL, O. P. D.; ASSISTANT SURGEON TO ST. BARTHOLOMEW'S CLINIC.

THERE are many abscesses of larger or smaller size which follow the infection of the genitals, and the treatment of which has not been satisfactory to me until lately. The abscesses to which I refer are suppurating glands in the inguinal region of both sexes, and abscesses of the vulvo-vaginal glands in the female.

The dissecting out of these glands is not always practicable, and requires an etherizer and one assistant. The opening of the glands by a free incision, thoroughly curetting and packing the cavity with iodoform gauze, and using a wet or dry dressing, is a long, slow way to recovery and disables the patient for several days. Patients coming to our clinics are of the working class, and generally are obliged to attend to their household duties or nominally appear at their work. If a small incision is made, which allows the patient to get about, and the abscess is packed with iodoform gauze, when the next dressing is done (in twenty-four or forty-eight hours) the gauze has become so saturated with the discharge and so adherent to the line of incision that the drainage is practically *nil*.

A more desirable dressing is one which will allow free drainage and can easily be kept in place. I have found narrow strips of gutta-percha tissue to answer this purpose admirably. My routine treatment now for suppurating vulvo-vaginal glands and inguinal adenitis is to make a small incision, depending on the size of the abscess—a larger incision for a larger abscess—to press out as much of the pus as will easily flow out, and to pack the cavity comfortably with long strips of gutta-percha tissue, about one-fourth to one-half inch in width, slightly twisting and folding the gutta percha as it is packed into the cavity, and to leave the end of the packing outside the wound. If the packing shows a tendency to work itself out, the end can be tucked within the incision. The opening will not close as long as the cavity is packed with gutta percha. For the patient I order ung. hydrarg., fifty per cent., with the instruction to apply the ointment liberally over the abscess morning and night, and cover with a cloth to protect it from the clothing. When the skin is tender, an ointment of equal parts of ung. ichthyol, ten per cent., and ung. hydrarg., ten per cent., can be used.

The packing is to be kept in twenty-four or, better, forty-eight hours; then the patient returns and a new packing is inserted. The patient is told to go about her regular duties. When she returns for the first dressing, it is generally with the report that she has no pain and can get about very comfortably. On removing the gutta-percha strips, one is struck by the clean, healthy, granulating appearance of the abscess; and this seems to have been brought about by the movements of the surrounding muscles, which keep the gutta-percha tissue moving about in the abscess cavity, gently curetting the abscess. The curetting work is done more satisfactorily if the incision into the abscess is not too long and the packing is not too tight. Rarely is it necessary to pack an abscess in this way more than two or three times, before the

healthy, rapidly growing granulations are ready to fill up the cavity. The packing is then discontinued, though the application of the ointment is kept up.

In using the packing the gutta-percha tissue should not be twisted too closely, but the cavity should be comfortably filled with partly twisted and partly folded strips of tissue. Better results are obtained when the cavity is not irrigated with an antiseptic solution before packing.

This mode of drainage has also been used most satisfactorily in deep infected wounds under strong fascia, as in the palm of the hand, even though these wounds are accompanied by a marked cellulitis. The drainage in these cases is much better than when iodoform gauze is used. The infected wound is opened thoroughly, packed with strips of gutta-percha tissue, and the surface is covered with a compress, kept constantly wet, of a solution of acetate of aluminum. The acetate of aluminum is made up as follows:

R Pulv. alum. 3 v.
Pulv. plumbi acet. 2 xxv.
Aque destil q.s. ad O iv.
M.

There is a precipitate when this solution is made up, and the bottle should be shaken before its contents are used.

The gutta-percha tissue is best prepared by being cleaned, then folded, and put into a 1 to 1,000 solution of HgCl_2 , in which it will keep indefinitely. When used, a strip of the folded tissue is cut off, unfolded, rinsed in plain water, and packed into the abscess, as above described. The gutta-percha tissue should not be used with carbolic solutions, as they destroy it.

Having used this dressing for abscesses for a year and more in my clinic at Roosevelt Hospital, with satisfactory results, and not knowing of its being used before, I suggest it for trial by others of the profession.

LARYNGEAL PAPILLOMA IN A CHILD—REPEATED INTUBATION—DEATH.

By F. LOHRSTORFER, M.D.,

FORT HURON, MICH.

T. P.—, aged three years. Ten months ago the parents first noticed some difficulty in the child's breathing, but attributed it to asthma. The obstruction gradually increased and when the child was brought to me it presented an appearance identical with that of one suffering from severe diphtheritic stenosis. The voice was whispering. A laryngoscopic examination was unsatisfactory on account of the fractious disposition of the patient, and a like attempt under chloroform nearly terminated fatally from suffocation. An intubation tube was at once inserted, with complete relief. Six days afterward the tube was removed, when dangerous dyspnoea at once supervened. This, however, soon passed off and in two or three days the breathing was quite free. The relief lasted four weeks, when stenosis again returned, worse than before. An O'Dwyer tube was again inserted. Four days later as the child was playing in the street it coughed the tube out and the dyspnoea became at once urgent. I then introduced a larger tube, which gave perfect relief. The child's condition was normal in every way except for its loss of voice. This third tube remained undisturbed for three weeks, when, fearing injury to the larynx, I administered chloroform and removed it. Instantly on its withdrawal the face

became cyanotic, the pupils dilated, and the most strenuous efforts of the patient failed to provide air. Tracheotomy was at once performed and the immediate danger was over. I had intended an operation for the radical removal of the obstruction on the following day, but in the night the child was suddenly seized with dyspnoea and died in less than a minute, probably from some obstruction in the cannula, although both inner and outer tubes were removed in succession by the attendants. The autopsy, twelve hours later, showed a broad-based papilloma entirely encircling the interior of the larynx at the level of the vocal cords and completely blocking the passage. In spite of the last intubation tube remaining in three weeks, there was not the slightest trace of irritation of the larynx or trachea.

CONGENITAL IRREDUCIBLE UMBILICAL HERNIA—DOUBLE UTERUS.

By JAMES HARVEY RAYMOND, M.D.,

WAILUKU, H. I.,

GOVERNMENT PHYSICIAN FOR THE DISTRICT OF WAILUKU AND ATTENDING
PHYSICIAN TO MALULANI HOSPITAL, WAILUKU, MAUI, HAWAIIAN ISLANDS;
FORMERLY INSTRUCTOR IN SURGICAL PATHOLOGY, RUSH MEDICAL COLLEGE,
CHICAGO.

ON June 7, 1895, Dr. Aiken, of Paia, Maui, H. I., asked me to consult with him in a case of labor. The patient was a Portuguese woman, a multipara, aged twenty-five years; she was apparently well nourished, and had a history of no previous illness. She had been pregnant twice before, and each time the fœtus was born dead. The first birth gave no trouble whatever, but in the second labor was prolonged and a physician had to be called to deliver the placenta.

On the 29th of May the woman called on Dr. Aiken, informing him that she was pregnant, and asked him for medicine to produce delivery. From remarks made by the woman in response to his questioning, Dr. Aiken suspected that the child was dead; he so informed her and advised a digital examination. Although she concurred in his suspicion, and also stated that on two previous occasions she had given birth to a dead child, she absolutely refused to allow an examination at that time.

Eight days later the doctor was sent for to attend the woman and upon examination found a dead fœtus. The patient refused to have the fœtus extracted until two days later, at which time I was called in. The face of the patient was blanched and wore an expression of great fatigue; she was perspiring profusely. Respirations rapid; pulse full and collapsing; temperature subnormal; fecal vomiting. The patient was anesthetized, and upon digital examination we soon determined that the fœtus had been dead for some time, as it was in a stage of advanced decomposition.

The cervical portion of the uterus was deflected to the left, as though it were drawn to that side by adhesions, and an exploration of the interior of the organ necessitated carrying the fingers well to the left to find the os.

The os would not admit more than two fingers, and to the left of it could be felt a circular depression, from three to four centimetres in diameter and about five millimetres in depth, with a smooth rounded edge and a hard base. The occiput could be felt to the left side, but it was impossible for the head to present, owing to the apparent distortion of the uterus.

I hooked my finger into the os and slowly dilated it, using considerable force, until it would admit the whole hand, when with comparative ease the head

came away, and the body and placenta were speedily delivered without difficulty.

The depression felt at the side of the patulous os was then found to be the os of a separate organ, which was entirely within the impregnated uterus and large enough to admit my hand on dilating it with moderate force. The hand could be passed completely around the abnormal organ from within the impregnated uterus, as it was attached only at the os.

The patient survived the anæsthetic, but died eight hours later of septicæmia, the symptoms of which were manifest upon my arrival.

Unfortunately, we were unable to obtain permission from the relatives of the deceased to perform an autopsy; therefore our deductions are more or less hypothetical. But, from the observed anatomical condition, we arrived at the conclusion that the abnormal uterus was nourished by the same blood-vessels, excited by the same nerves, and consequently enlarged concomitantly with the pregnant uterus, and that it caused the death of the fœtus by mechanical pressure.

A MONSTROSITY.

By J. M. FRANKENBURGER, M.D.,

EDITH, COL.

ON April 15, 1896, I was called to attend Mrs. A., aged forty, mother of three children, the youngest of whom was five years of age. I found her having slight labor pains, the membranes having been ruptured about half an hour. On palpation the position was made out as being a breech presentation, head to the left. Vaginal examination revealed nothing, the parts still being too high up. I tried turning by external manipulation, but was unable to accomplish anything, and concluded to let the case alone until something further developed. The pains were very slow and irregular, and no progress was made in the labor for about ten hours, when on making a vaginal examination I could clearly make out the presenting

FIG. 1.

parts. But the puzzling part of the examination was a mass of something feeling like intestines which I could detect just inside the os. There had been very little hemorrhage. I could tell by the sense of touch that it was not placenta, and I was completely non-plussed. Labor progressed slowly, and one-half hour before the child was born I could detect no fetal-heart sounds. About twenty-four hours after labor had set in, my patient had a severe pain, and the mass before mentioned, fœtus, and placenta came away together.

Fig. 1 shows the fœtus as it appeared at time of birth, before any dissection was made. Dissection was as follows: Weight of fœtus, six pounds; head well developed, the bones of the skull being freely movable, so much so that the head could be pressed together until one-half the original size. Lungs very small, but complete. Heart very small, the left ventricle being almost as large as both auricles and the right ventricle combined. Below the diaphragm there was absolutely nothing in the abdominal cavity (or what should have been the abdominal cavity) except two small blood-vessels, which ran to the lower extremities. There was no evidence, either internal or external, of any organs of generation or anus, there

FIG. 2.

being no break at all in the skin. From the umbilicus there was suspended a bag or pouch containing all the abdominal organs, which was the mass I could feel during labor. A long tube-like continuation of the œsophagus extended to the stomach, which was quite large. The rectum was smaller than the small intestine, and had no opening at all. There was but one kidney, and about one-half an inch of ureter between it and the bladder. The liver, spleen, and pancreas were normal. The umbilical cord was but three inches in length, and ran through the pouch. The left hip was dislocated. Both feet were in a position of talipes equino-varus.

Fig. 1 shows the entire continuity of skin between the legs, and also the dislocated hip. Fig. 2 shows the talipes, the pouch cut open, the intestines and liver exposed, and the approximation of it to the placenta.

I present this on account of the peculiar development, or rather non-development, especially of the abdominal organs, all being outside of the abdominal cavity, and the absence of organs of generation, these being ordinarily among the first to develop.

Suicide is very common among Russian physicians, due, it is said, to the hard struggle they have against the competition of free and heavily endowed dispensaries. Fees are often ridiculously and tragically low, sometimes, according to *The Lancet*, only twenty kopeks or six cents for an office consultation.

The Fundamental Treatment of Disease is what Malcolm Morris dubs official surgery.

REPORT OF A CASE OF RECURRENT BASILAR MENINGITIS, WITH RECOVERY.

By HENRY M. KOLES, M.D.,

NEW YORK.

ON account of the number of attacks resembling a meningitis at the base of the brain which this patient has suffered from, together with the rapid response to antisyphilitic treatment, and the positive assertions on his part as to never having been affected with this specific malady, I deem it of sufficient interest to put a detailed history of this case on record.

X. Y—, twenty-three years of age, medium height, well nourished, had never suffered from any serious illness until his seventeenth year, except that when a baby he had had measles and what was then regarded as rheumatism. His parents are living and healthy; neither one gives a history of any protracted illness; his sisters are living and all are healthy. X— was a proficient scholar at school and at fifteen years of age left it to enter business; at seventeen years of age he held the position of clerk in a wholesale establishment, where he spent his spare moments in wrestling with his companions. During one of these bouts he

was thrown violently against the edge of a table and rendered unconscious. When he recovered he vomited, had a severe headache, and required the assistance of his comrades to lead him to his home, where he was confined to the bed for several weeks, suffering with severe headache in the frontal and parietal regions and general weakness. A few months after recovering from

this attack, while doing some heavy work, he suddenly experienced headache severe enough to compel him to discontinue work and seek his home. On his way, when a short distance from his place of business, he had an attack of vertigo and fell to the ground. He was taken to a neighboring drug store, where restoratives were administered. As soon as he felt sufficiently revived he essayed to rise and walk away, but he was unable to do so. He was then taken in an ambulance to Chambers Street Hospital, where he remained until the next morning, when his anxious relatives called for him. He was confined to his bed for many weeks; as nearly as he can remember it was more than two months before he recovered the partial use of his right arm and leg, which had been paralyzed. He thinks that there was a slight facial paralysis but is not certain. He was conscious all of the time, did not vomit, appetite was fair; he passed urine regularly, was slightly constipated; the special senses were unimpaired. He was able to return to work and for two years was almost entirely well. He then began to have attacks of headache, which compelled him to take to his bed for several weeks at a time, and rendered him unfit for work for several weeks more. These headaches, which recurred about every six months, were usually preceded by an attack of vomiting. The location was over the frontal and parietal regions of the left side. He could not sleep, and his moaning and shouting were loud and prolonged.

About a year ago he acquired a blennorrhœa and was referred to me for treatment by one of his friends. After a protracted siege he finally recovered and enjoyed comparatively good health for several months. Six or seven weeks ago I was hurriedly sent for by the

young man. I found him in bed with one of his accustomed attacks; he was complaining very much of pain in the front and left side of the head and was very restless; the face was flushed, the eyes were injected, the tongue was coated; temperature, 101° F.; pulse strong, rapid, and full. He had an attack of vomiting just previously to the onset of the headache, which otherwise was sudden and abrupt; during my stay he vomited some fluid matter containing mucus and bile. I prescribed some calomel to relieve the constipation, bismuth and bromide mixture, together with absolute rest in bed, ice to the head, and restricted diet. In the course of a few days the symptoms subsided and he returned to business; he had not been there more than a few hours, however, when he suddenly became faint, and then was attacked by dizziness and nausea. He required assistance to reach his home and to be put to bed, where he was seized by a fit of uncontrollable vomiting, which did not cease until his entire breakfast had been voided. I found him about an hour later suffering with headache and nausea; the face was flushed and anxious; the pulse was rapid; temperature, 101° F.; the extremities were cold; the breathing was labored and increased in frequency, and the head was drawn backward and to one side. This attack was similar, I was told, to all his previous ones and his folks were not alarmed, but expected it to pass away just as the others had done before. A careful examination of the heart, lungs, and abdominal organs revealed nothing abnormal. I refrained from stating to his relatives that I thought we had to do with a meningitis, not desiring to alarm them. I prescribed some phenacetin and bromide of potassium, ice cap to the head, and enjoined perfect quiet and rest. The condition on the next day was about the same: temperature, 100° F.; pulse, 110, but weaker than on the preceding day. He complained of a pain in the abdomen together with the violent throbbing pain in the head, which rarely left him, and if it did was followed soon after by one of increased severity. There was also pain in the back of the neck, but no rigidity. He preferred to keep his head drawn backward and to one side; he had slept but little. I combined small doses of morphine and chloral with bromide of potassium, which, however, gave but transitory relief.

On the morning of the third day following the attack, in addition to his other trouble, he complained of pain in his abdomen more severe than heretofore, and constipation; there was no tympanites, no point of tenderness, and the administration of an ox-gall enema was followed by a copious stool and entire relief of abdominal pain. Temperature in the evening was 102° F.; pulse, 120; rigidity of muscles of the neck was marked and pain quite severe. Pain in the head, which recurred at intervals, was so severe as to cause him to moan and even to shout. His tongue was coated; the skin was hot and dry.

A hypodermic injection of one-fourth grain of morphine relieved his pain for several hours and he was enabled to sleep. His condition remained about the same for two days, the only improvement, however, being a partial cessation of the pain in the head. His appetite was not impaired; he took only fluid nourishment—milk, broths, and eggs. He still continued to take morphine, bromide, and chloral for pain and sleeplessness, with ice caps to back and head constantly; besides this, he was put on iodide of potassium in increasing doses. His bowels moved once in twenty-four hours. The urine was acid and deep amber in color; specific gravity, 1.018. It contained no albumin, no sugar, no casts. Temperature, 101° F.; pulse, 120, weak. The pupils were slightly dilated, not over sensitive to light; the special senses were unimpaired.

Fifth day.—Temperature, 102° F.; pulse, 125. Slight double exophthalmus became apparent; the pupils were dilated, and there was beginning internal strabismus of the right eye. The muscles of the back of the neck were markedly rigid. He took nourishment regularly and was interested in everything going on about him. He answered questions readily and correctly. Morphine and bromide were diminished and iodide was increased; he was taking one hundred grains of the latter in twenty-four hours.

Sixth day.—He passed a restless night with very little sleep, and shouted a great deal. The strabismus was more marked. There was slight ptosis; the pupils were dilated; the tongue was dry, rough, and coated. Temperature, 103° F. Pain was severe. He tossed about in bed a great deal, and complained of pain radiating from the shoulder down the arm. He took nourishment when offered and after an interval answered questions. Sensation and special senses were not impaired.

Seventh day.—Temperature, 103.5° F.; pulse, 125; respiration labored, sighing; tongue dry and coated; sordes on teeth and lips; internal strabismus of the right eye complete; pupils dilated, not responsive to light. He shouted incessantly and did not reply to questions so readily as before. Morphine and bromides seemed to have but little effect. The neck was rigid and immovable.

Eighth day.—Condition worse than on preceding day. Pulse, 140, vibratory, weak; temperature, 103° F.; Cheyne-Stokes respiration, sordes on lips and teeth; carphologia. He shouted continually and was maniacal. There was beginning strabismus of the left eye and exophthalmus of both. He was very restless and delirious part of the time.

Ninth day.—I considered his case hopeless. Temperature, 103° F.; pulse, 140, weak, irregular; respiration slow, labored, Cheyne-Stokes. Complete converging strabismus of both eyes, ptosis, pupils widely dilated, facial paralysis (left). There was beginning difficulty of deglutition. He was delirious most of the time. Morphine, two grains during twelve hours, together with bromide and chloral and hyoscyamine, had very little effect. Believing firmly that the end was approaching and desiring to satisfy the parents as to the correctness of the diagnosis and method of treatment, I received their consent to a consultation with Dr. Alfred Wiener, who was kind enough to see the patient with me late that evening. After carefully going over the case, he found by ophthalmoscopic examination, in addition to the symptoms enumerated above, choked discs and a hemorrhage in the retina of the right side. The conclusion arrived at after the examination was that the chances for recovery were very slight if any, and the parents and friends were notified of the patient's impending fate. I administered fifteen minims of Magendie's solution with atropine, ordered the iodide increased, and at the suggestion of Dr. Wiener prescribed some ten-per-cent. oleate of mercury to be rubbed in the skin over the muscles of the neck and the iodide of potassium to be given in increasing doses.

The next morning I saw but little change in the patient. He swallowed with more difficulty. Temperature, 103° F.; pulse, 130. He took nourishment, was apathetic and delirious by turns, and answered but few questions. He received four injections of morphine and atropine in twenty-four hours, one-half grain each time, and sixty grains of iodide of potassium four times daily, together with mercury inunction, alcohol bath, and ice applications. This treatment was persisted in for several days.

The looked-for end did not materialize: on the contrary, he gradually improved after he had been taking three hundred grains of iodide per day and

mercury inunctions for several days. He was growing more rational, answered questions more readily, recognized persons and actions at his bedside. The Cheyne-Stokes respiration gave way to normal: pulse became stronger and less rapid (100); temperature, morning 99° F., evening 100° F. Facial distortion faded away, mobility of the eyeballs was increased, and in the course of several weeks he was able to sit up. Rigidity of muscles of the neck was overcome completely. The appetite improved, the bowels became regular, and morphine was discontinued. The point of tolerance for iodide was reached when he was taking a little more than three hundred grains daily.

Taking this history into consideration, the first thing that attracts our attention is the hemiplegic attack from which this patient suffered at the commencement of his illness. Whether this was due to an embolism or to a thrombosis can hardly be established on firm grounds. Taking the early history of rheumatism into account, the early age at which the apoplectic attack took place, the mild onset, there being no complete loss of consciousness, we would be inclined to think of embolism. A careful examination (physical) of the patient furnishes no source for the production of such an embolism.

With regard to thrombosis it may be said that through an early infection of syphilis the arteries may after all have been in a diseased condition and thus favorable for such a thrombosis to form.

With regard to attacks of headache, vomiting, and fever with slight rigidity of muscles of back of neck, which this patient suffered from, although I did not see him at these various times, I do not hesitate to say that these attacks were undoubtedly due to meningeal irritation.

The last attack, which I have carefully recorded above, demonstrated beyond a doubt that we had here to deal with a meningitis which localized itself in the neighborhood of the interpeduncular space and in the region of the pons and medulla.

Whether this pathological condition was in the form of a syphilitic meningitis or of a gummatous infiltration cannot be positively set down as a fact. I am inclined to believe that it was in the form of a meningitis, first, on account of its spreading nature, and second, on account of the fever which attended the attack.

The rapid response to heroic anti-syphilitic treatment in this case, the gravity of the symptoms being considered, establishes beyond a doubt that the nature of the pathological condition existing at the base of this patient's brain was truly specific in character.

TO DRAW THE CORK OF A TABLET BOTTLE.

BY D. W. EVANS, M.D.,

DELL RAPIDS, SO. DAK.

IN taking a look at the small bottles which are used to contain hypodermic tablets and having demonstrated the impracticability of pulling the cork, especially when one is in a hurry, as one is likely to be when called upon to use the hypodermic syringe, I have devised a method by which the cork is never broken, neither is the bottle broken, in the attempt to remove a refractory cork that one has accidentally pushed in too far. As most corks are nearly the same in diameter throughout their entire length, I take a common sewing-needle and thread it double with No. 8 thread, having first tied two knots on the end. I force the needle through the cork, beginning at the smaller end and piercing it lengthwise, then knot the thread again at its point of exit in such a manner that it cannot be drawn back. Then I tie a knot about one-half

inch from the last knot and clip off the thread. I now have a cork that can be drawn out at any time, even if it has been pushed in too far. The thread is always ready to pull upon, and is clean, neat, and very handy and inexpensive.

FOREIGN BODIES IN THE MALE URETHRA.

BY HARRY C. HAYS, M.D.,

TOLEDO, OHIO,

ASSISTANT PHYSICIAN, TOLEDO STATE HOSPITAL.

OUTSIDE of an institution for the care of insane patients, foreign bodies in the male urethra are not very common, aside from the infrequent cases observed in small boys whose spirit of curiosity and investigation is worthy a higher aim, and an occasional accident, self-inflicted or otherwise, to a man while intoxicated. In most cases it is generally understood to be an indication of a more or less unstable neurotic temperament, which has as its motive the excitation or gratification of that sexual passion which is either perverted or has been so abused that its normal manifestation is impossible.

The following case is interesting, in that it shows to what extent it may be practised by insane patients and how long the real trouble may be concealed, even when the physical suffering and mental distress is great, if the physician in attendance fails in his duty of making a careful physical examination, as is so often the case with this class of patients outside hospital treatment. John R.—, aged sixty-five, German; occupation, farmer. Form of mental disease, chronic melancholia; duration of insanity, several years. The patient came under my charge from the care of another physician, who thought he was aware of the real nature of the trouble existing, respecting the genito-urinary system, and had pronounced it hypertrophy of the prostate, but had taken no steps to relieve the suffering, although he had had charge of the case for over a year. The clinical signs and symptoms were simply those of great pain and distress when micturition was attempted, the flow of urine being slow, interrupted, and at times suddenly stopped altogether, with intense pain in the glans penis. The necessity existed of passing water very often both day and night. The symptoms, as a matter of fact, were typical in all respects of stone in the bladder.

On attempting to pass a sound an obstruction was met immediately after entering the external meatus. This first foreign body could be plainly felt by taking the penis between the thumb and forefinger, and no great difficulty was experienced in extracting with a pair of simple artery forceps what proved to be a piece of rubber tubing or catheter about one inch in length with a diameter of one-quarter of an inch. It was covered with a deposit of urinary salts; but the lumen of the tube remaining open and lying lengthwise in the urethral canal allowed the urine to pass through without difficulty.

Passing the sound still farther, a second obstruction was met and its distal end found to be located at or near the peno-scrotal junction. This was easily detected on manipulation and seemed to be about three to three and one-half inches in length. Evidently either two foreign bodies were lying side by side, or one was turned upon itself and lying in the long axis of the urethra, as was the first. On grasping this with a pair of forceps and attempting its extraction, it was found that when traction was made the two ends moved forward at the same time, although only one seemed to be caught between the blades of the instrument. Finding that the loose end was in danger of penetrating through the urethral wall into the sur-

rounding structure, an incision was made to the urethra, the foreign body serving as a guide, and with a pair of small forceps a large-sized hairpin was withdrawn. This was also covered with a deposit of urinary salts and rust, showing that it had been in the urethra some time.

Introducing the sound finally into the bladder, the unmistakable and characteristic click was produced which indicated stone.

The patient was allowed to recover from these two slight operations, and after getting him into as fair condition as possible the median operation of lithotomy was made, with the result of extracting a stone weighing four hundred and nine grains. It was of the mixed or fusible variety of phosphatic calculi, on breaking up which its nucleus for deposit was found to be a piece of fine iron wire, coiled upon itself, and measuring in length when straightened out five and one-half inches.

This was as far as I thought practicable to pursue the investigation in this case, but our curiosity was aroused to the degree of wondering if perchance something more might not be discovered, either in the ureters or in the pelvis of one or the other kidney.

The patient, notwithstanding his age, condition, and length of time of his distress, made an uneventful recovery. The only thing necessary now is to pass a sound occasionally, to be assured that he has not introduced something more into his urethra.

UNION OF A SEVERED FINGER TIP.

By W. V. GAGE, M.D.,

M^CCOOK, NEB.

ON Monday, February 17th, the patient, E. W.—, while applying a lubricant to the chain of his bicycle, had the misfortune to catch the index finger of the right hand between the chain and the rear sprocket of the rapidly revolving wheel. The pressure of the opposing surfaces completely severed the finger at the root of the nail, cutting through the middle of the last phalanx. The accident occurred in a bicycle store, a block from my office, and a few minutes after the patient was under my care. On examination I found that there was not sufficient uninjured tissue to make suitable flaps, and a temporary dressing was applied, in view of an early operation, when it was my intention to shorten the bone so that I could utilize the tissue for flap coverings. About half an hour after the patient arrived in the office, one of the young men of the town brought me as a curiosity the severed end of the finger, wrapped in a piece of tissue paper. The fragment had passed through several hands since the accident, and had been used as the subject of one or two practical jokes, before coming into my possession, and was covered, as had been the hand of my patient, with dirt and oil deposited during the bicycle-cleaning process. Although realizing that there was little hope of success, I scrubbed the fragment with soap and water, and immersed it in a five-per-cent. carbolic-acid solution; I removed the dressing I had just placed, and fixed on the end, pushing the matrix of the nail which remained on the severed end well under the tissue, and then replaced the dressing. I did not suture, as I did not wish to cut with the needle any small artery which might possibly furnish a source of nutriment to the severed end. Thirty-six hours after the accident I applied two narrow strips of adhesive plaster, crossing each other at right angles over the end of the finger, to guard against any possible accident from a slight blow, and dressed with iodoform and five-per-cent. carbolic-acid dressing. The end at the time looked white and lifeless, and

there really seemed to be little chance of union taking place. The process of healing took fifty days; the skin and a small amount of the superficial tissue on the end of the finger dried and separated before union was complete.

TRAUMATIC PERITONITIS AND RUPTURE OF THE BLADDER.

By CARL C. WARDEN, M.D.

ISHPEMING, MICH.

JOSEPH C.—, twenty-three years old, woodsman, came to the hospital at midnight on April 8, 1896. He had been drinking heavily all day and had been unable to urinate since four o'clock in the afternoon. One hour before admission, during a drunken brawl, he was twice kicked in the abdomen. The patient complained of great pain in the hypogastrium and was in a condition of partial collapse.

Examination showed a small ecchymotic area in the right iliac region, the abdomen much distended and painful, and the bladder rising above the umbilicus. Catheterization brought away sixty-four ounces of bright bloody urine.

The following morning at seven o'clock the patient's condition was not improved. Forty-eight ounces of urine tinged with blood came away by the catheter, giving the man no relief. Distention and tympanites were evident. The patient developed a general peritonitis. Subsequent catheterizations brought away a normal quantity of urine unmingled with blood.

On the evening of April 10th only a few drops of thick dark-colored urine could be obtained. The man died early on the following morning.

The autopsy showed the abdominal cavity filled with serum, the intestines distended, agglutinated, and covered with patches of lymph. A portion of the ileum lying in close relation to that portion of the abdominal wall which received the blows was gangrenous to the extent of four inches. The kidneys were normal and both ureters intact. The bladder was partially filled with clear urine. At the fundus of this organ was found a complete laceration, one and a half inches in length, running posteriorly. The edges of the tear were uneven and gangrenous. The organ was otherwise in a perfectly healthy condition.

A diagnosis of rupture of the bladder was not offered without reservations. The quantity of urine drawn off at regular intervals during the man's sickness would indicate that the bladder retained its contents perfectly, and consequently the peritonitis could not have taken origin from leakage of urine but from the lesion of the gut alone.

It seems probable that the rupture of the viscus extended primarily through the mucosa and muscularis coats, the serous covering remaining intact until a few hours before death.

Calomel Hypodermically.—The calomel is blended with sterilized oil, and every precaution observed to prevent infection with the needle. A long, strong needle is used and the fluid is injected deeply into the tissues of the right loin. No suppuration or nodosities follow. The maximum dose of calomel by this plan is five centigrams, about one grain. By this method the patient is spared the pain and inconvenience of stomatitis, and, besides, the action of the drug is more energetic and decisive.—*Therapeutic Review.*

POISONING BY CANNABIS INDICA.

BY MARY L. GEISER, M.D.,

FORT MADISON, IOWA.

HAVING read the case of cannabis-indica poisoning reported in last week's MEDICAL RECORD, by G. G. Fischlowitz, M.D., and noticing that not many cases have been recorded, I will report a case of poisoning by the same drug, which occurred in my practice August 13, 1896. The patient, Miss M. C.—, aged fifty-seven, suffering from malarial cachexia, began on July 6th to take $\mathfrak{m}$ v. of normal liquid cannabis indica which I had prescribed for migraine. On August 12th I increased the dose from $\mathfrak{m}$ v. to $\mathfrak{m}$ vii. The first prescription was dispensed by a druggist who has the reputation of substituting. The patient called after having a second prescription filled and we examined it, the patient stating that it did not resemble the first in color or taste, the first being light colored and of pleasant flavor. (It was suspended in simple elixir.) The first dose was taken about 11:45 A.M., August 13th; the patient ate dinner about twelve o'clock and was taken suddenly and violently ill a few minutes before 1 P.M. The first sensation was that of fainting, and the patient went to the door for fresh air. A feeling of numbness and tingling of the entire body rapidly supervened, with much difficulty of breathing. Being in the neighborhood, I saw her in less than five minutes; at that time she was seated in a chair, her expression being staring and somewhat anxious. The apnoea grew worse. The patient said she felt paralyzed and very weak. Two or three times she seemed to lose consciousness; at those times the pulse was very weak. She was able to lie down most of the time, though at times we were compelled to hold her up to facilitate respiration. I gave her one-fortieth grain of strychnine and one-tenth grain of apomorphine hypodermatically. Before emesis took place I gave her a second one-fortieth grain of strychnine. Emesis now began and she was somewhat relieved. She was given copious draughts of hot water to thoroughly wash out the stomach. Twice after this she sank and was given each time one-fortieth grain of strychnine; the last dose being given about 3:30 P.M. It was about 4:30 P.M. when I thought she was well enough to be left, though there was still some sighing respiration. She did not go to sleep until after 8 P.M. and spent a rather restless night. She felt quite weak for some days and does not yet feel as well as usual.

The apnoea and extreme weakness were the chief symptoms. The patient experienced none of the feelings which are thought usually to attend poisoning by cannabis indica. Her mind was clear, except when for a few moments she was unconscious. The time did not seem especially long; she felt entirely herself; did not feel dizzy; was able to hear and understand all that was said to her; answered all questions perfectly, though her voice had a faint far-away sound. Sight seemed to be more affected than any other sense. The patient said she felt at a distance from us and also felt at different times as if she were dying; these feelings occurred just as she was losing consciousness. The urine was not changed.

I believe that if my patient obtained any cannabis indica in the first mixture it was inert, and in the second she received a larger dose than she could bear by not coming up to it gradually, as I had intended she should.

August 27, 1896.

Rupture of the Kidney.—Dr. C. K. Toland recently reported a case of rupture of the right kidney in a young man of nineteen years, who had been "charged and kneed" by an opponent while playing football.

New Instruments.

GLASS DOUBLE-CURRENT IRRIGATING TUBES.

BY ROBERT COLEMAN KEMP, M.D.,

NEW YORK,

SURGEON TO THE CHURCH INFIRMARY AND DISPENSARY.

THE glass rectal irrigator is a tube five inches long, shaped like a rectal bougie. The central tube opens into the bowel at the tip of the instrument. There are two openings, about half an inch posterior to the tip, for the return current, which passes on all sides of the central tube and flows out of a single collecting tube below. Above the point of exit for the return current

is an opening for cleaning the instrument. This is closed by a cork. Some of the glass tubes are made without this opening, and in

these the central tube is of large calibre, being used for the return current, the ingress current entering laterally. These are not so readily cleansed. When the return current is made to pass through the central tube, only a small amount of water will pass up the bowel, as the return will be nearly immediate. By varying this and by pinching the entering and return tubes, the quantity of water can be regulated, as described in the MEDICAL RECORD, December 7, 1895. These glass tubes are made in two sizes: No. 1, diameter one-half an inch; No. 2, di-

ameter five-eighths of an inch. They can be bought of the instrument makers in this city.

The double-current surgical irrigating tube is about ten inches long, made of tough glass, either straight or curved. It is in effect a double-current Chamberlain tube, and can be used as a simple irrigating tube; or, on the siphon principle, to wash cavities; or, with the direct return, to wash large sinuses. The tubes are made closed, or with the cork opening for cleansing purposes, as in the glass rectal irrigators. The closed tubes should allow the entering current to pass out laterally, and the return current to pass through the centre. The curved tubes have the large entering tube on the concave side, to act as a handle and also as a guide to the curve. They are made in two sizes, No. 1 and No. 2, the same as the rectal.

Progress of Medical Science.

The Effect of Laparotomy on Tuberculous Peritonitis.—Dr. Gatti (*Il Policlinico*, March 28, 1896) has experimented on dogs, guinea-pigs, and rabbits in order to determine the value of laparotomy in the treatment of peritoneal tuberculosis. He concludes that laparotomy has little effect when the tuberculosis is quite initial. The tuberculosis presents no macroscopic changes in the first three to five days after operation, but a small quantity of reddish serum is thrown out. From seven days to nearly a month the tubercle was almost always increased in amount, but after this diminution and disappearance were noticed. Cure occurs through a degeneration of the epitheloid cells, without the intervention of wandering cells, independently of phagocytosis and without the formation of fresh connective tissue. Dr. Gatti thinks the serous fluid which is thrown out the first few days stimulates the repressive processes after laparotomy: this is effected by the serous fluid bathing the tuberculous mass, however thick, and having a bactericidal and attenuating action on the tubercle bacilli.

Hypertrophy of the Prostate.—Dr. Glenn (*Southern Practitioner*, July, 1896) summarizes as follows: 1. Prostatic hypertrophy is a disease of old age, seldom giving trouble under forty-five years of age. 2. Prostatic hypertrophies are divided in two classes: those slightly enlarged, with some residual urine, some interference with the force of the stream and recurrent attacks of cystitis; and those very much enlarged, with decided deformity of the urethra and inability to urinate voluntarily, the bladder emptying itself only by the aid of the catheter. 3. Subjects with the first variety should keep up careful and systematic dilatation with metallic bougies and empty the bladder with the catheter once daily. The second class should at once be submitted to surgical treatment for radical cure. 4. A safe and efficient means of giving relief to urgent symptoms is by puncture through the perineum, which may be done without an anæsthetic or with cocaine. 5. In operating for radical cure pedunculated middle lobes should be removed by electric cautery, or *écraseur*, not with scissors or knife. If not pedunculated the hypertrophied portion should be gouged out with the finger after the mucous membrane is thoroughly incised.

Local Treatment of Gout.—Dr. William Murrell (*Lancet*) gives the following method, which he has employed with success: "I take half an ounce of iodide of potassium, dissolve it in half a pint of rectified spirit—methylated spirit is used in hospital practice—add one ounce of soap liniment, and then one-half drachm each of oil of cajeput and oil of cloves. A piece of lint is soaked in this mixture, wrapped round the affected part, covered with a protective, and kept in place by a bandage. It acts as a powerful counter-irritant, and the inflammation usually subsides in from twelve to twenty-four hours. In addition, I not uncommonly give a drachm of colchicum wine with ten grains of iodide of potassium three times a day. These large doses of colchicum wine induce brisk purgation, sometimes accompanied by vomiting, but they speedily cut short the attack. This mode of treatment is especially useful in the case of robust, full-bodied men in active employment, to whom the loss of a day's work is a serious consideration. In sciatica, lumbago, and rheumatism affecting one joint the local application of a liniment containing half an ounce of salicylate of sodium, half a drachm of oil of cajeput, fifteen minims of oil of eucalyptus, and half an ounce of soap liniment in six ounces of rectified spirit affords prompt relief."

Extirpation of the Rectum by the Kraske Method.—Dr. Joseph Bacon says that when the cancer or stricture is limited to the anus and lower rectum it frequently happens that the diseased portion can be removed without opening the peritoneal cavity, and in such cases the danger of the operation is reduced to a minimum. Unfortunately cancer of the rectum, like stricture, usually begins at a point where the levator ani muscles encircle the rectum, and when the growth is removed the greater part of the levator ani muscles and the recto-vesical fascia, together with the peritoneal covering, is so extensively removed that resuturing of the peritoneum so as to close the peritoneal cavity is out of the question, and one must close the abdominal cavity by means of gauze packing in the pelvic outlet, until after four or five days, when the peritoneal surface next the gauze will have thrown out a layer of lymph and granulation tissue, entirely closing off the peritoneal cavity from the external wound. It is important to remember that the bony incision must be limited above at the lower border of the third sacral vertebra, otherwise the third sacral nerve is injured and serious bladder complications are brought about by the paralysis of this nerve.—*Interstate Medical Journal*, April, 1896.

Treatment of Pneumonia in Infants.—Dr. L. Emmett Holt (*Archives of Pediatrics*, xiii., No. 4) gives the following method in use at the Babies' Hospital, New York: Among the children under three years of age treated at this hospital, one-fourth of the pneumonia cases are lobar, three-fourths bronchopneumonia. The cases are kept in a ward by themselves, with plenty of air space, temperature 70° F., and the children are removed once a day to permit a thorough airing of the ward. To secure proper nutrition, and to avoid digestive disturbance, food is given considerably diluted, and at regular hours; also abundant water between times, with stimulants. Peptonized milk is used for the youngest infants. Care is taken to avoid distention of the colon by gas, which frequently occasions cyanosis or convulsions in infants. Daily irrigation of the colon is practised in such cases. Drugs are to be avoided and especially expectorants. Antipyretics are to be used only when there is a high temperature, with extreme nervous symptoms. Cold sponging, ice to the head, or the cold pack or bath are freely used, and occasionally phenacetin. Counter-irritation by a mustard-and-flour paste of the strength of one to six, applied for a few minutes three times a day, is much more useful than poultices. Inhalations of steam from a croup kettle under a tent are employed systematically in all cases every three or four hours. The steam is charged with vaporized creosote, turpentine, or benzoin. The inhalation is continued from ten to twenty minutes, and controls the cough. For stimulation, from one-half to three ounces of whiskey are administered every twenty-four hours well diluted; strychnine in frequent small doses; sometimes nitroglycerin, or digitalis and ammonia. An oil-silk jacket should be worn. Prolonged cases do better when sent away to the country than when retained in the hospital wards.

Cold Baths in Delirium Tremens.—We read in *La Presse Médicale*, 1896, No. 4, that cold baths are very effective in quieting even the most violent attacks of delirium tremens. The temperature of the water should be 18° C. The patient is placed in the water up to his shoulders, and it is poured over his head. The bath is repeated two or three times the same day. This treatment has given surprising results in two cases in which all other measures were ineffectual. A few glasses of warm wine were given afterward, followed by quiet sleep.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 10, 1896.

THE LADIES' HEALTH PROTECTIVE ASSOCIATION.

WHAT may be done by earnest women in the way of health reforms is well illustrated in the account given, in the *New York Medical Times*, by Mrs. Ralph Trautman, the president of the Ladies' Health Association, of twelve years of work of that organization. The reason for the initiatory proceedings is thus significantly stated:

"In November, 1884, eleven women, residing on Beekman Hill, whose houses are beautifully located on a high bluff overlooking the East River, with everything desirable to make them healthful, were so outraged at the continuance of the foul odors which polluted the atmosphere of the entire neighborhood, causing them to keep windows closed in the hottest weather and depriving them of their inalienable right to pure air, that they resolved to investigate the cause of this nuisance.

"Accordingly, they made a tour of the neighborhood, in that section of the city known as the Abattoir District, which runs on First Avenue from Forty-third to Forty-seventh Street. Their first visit was a revelation, and while they returned to their homes ill from the inspection and the discovery of the nuisance by which they had so long been tortured, they decided that some action must be taken to better the condition.

"The following morning their number was increased to fifteen, and it was resolved that these women should form themselves into an organization, to be known as the Ladies' Health Protective Association."

The first action of the new society was to appear before the Grand Jury, and procure an indictment against the nuisance. Notwithstanding the strong political pull of the proprietor, who was the brother-in-law of a State senator, a verdict was secured against him, and he was compelled to employ a large force of men promptly to remove the foul and reeking nuisance. The earnestness and impartiality of the association was a matter of surprise to the then health authorities, and the gentleman who was president of the health board at that time was forced to admit on the witness stand that he had neither visited nor had a report of that section for six years!

In close proximity to the manure ground were the slaughterhouses, and adjoining the latter was a notoriously offensive bone-boiling establishment. A di-

rect appeal was made to the legislature for the abolishment of the former establishments. As might have been anticipated, the measure was defeated; but the large amount of money it cost the butchers to effect the object caused them to recognize the facts that the women were in earnest and were not to be overawed either by interested parties or by the political backers of the latter. The men who first came to scoff afterward remained to pray, and the result was a conference and consequent compromise. It was then discovered by the butchers, in consideration of the fact that the demands of the society were so great, that it would be cheaper in the end entirely to reconstruct their slaughtering-pens than to undertake the necessary alterations. Growing out of this determined effort on the part of the association, abattoirs have been constructed which are a credit to the builders and which in every way fulfil the advanced requirements of sanitary science.

The bone-boiling establishment was next dealt with, and after a valiant fight on the part of the determined reformers the firm was eventually forced out of business.

Duly encouraged by such good results, the association took up other matters, which had been more or less neglected by the authorities having them in charge. The gas-house nuisance was largely abated, the sanitary condition of stores, public conveyances, and public places was insisted upon, and the exposure of meats in thoroughfares was prohibited, through their instrumentality, by a special health ordinance.

We are informed in this interesting report that efforts are now being made to prevent exposure of all articles of food to the influences of the dust and dirt on the streets—a very proper and sensible measure, and one demanding the immediate attention of the health board and police authorities.

We heartily congratulate the association on the magnificent showing of good work accomplished along these and other lines, and trust that it will gain strength and wisdom in well doing. The great hope in its future efforts rests on the fact that it is not afraid of the so-called political bosses, that no special political pull can result in pigeonholing complaints, and that its members, being women, are naturally entitled to be heard on any subject in which they may be interested. We only wish it were within the province of these earnest and good women to attack the Hunter's Point stench nuisance, which has vied for years with the other outrageous abominations in the immediate vicinity of their headquarters. The members of the association could give valuable testimony at the pending investigation by the State health board.

THE COMMON DISEASES OF THE ANUS.

THE "Causes and Treatment of Some of the Commoner Affections of the Anus" are discussed by Dr. D. H. Goodsall, in a recent number of *The Practitioner*. The common diseases, he says, are abscess, eczema, fissures, fistulæ, venous pile, ulcers, syphilis, œdematous skin, and cancer.

As to abscess, very few hints as to treatment are

really needed, for there is but one way to take care of such a condition. The abscess cannot be opened too soon, and the incision which gives the most satisfactory result is the T-shaped, with its horizontal part parallel to the anus. Abscesses in this part of the body are generally left too long before being opened, and when opened the incision is usually far too small.

Eczema is, perhaps, one of the commonest of the troubles in this region, and is often associated with pruritus. It is caused by an absence of cleanliness, by constipation, by the passage of rectal mucus, by a discharge from the fistula, and by the discharge from the wound of the part. The treatment recommended by Dr. Goodsall is to cleanse the part thoroughly with olive oil and dry cotton wool, and then a liniment composed of sixty grains of powdered zinc oxide, one drachm of camphor liniment, and six drachms of lime-water liniment is gently rubbed over the surface for about five minutes. The parts are then covered with a layer of dry absorbent cotton. When the surface has become dry, a powder composed of oxide of zinc and camphor, one drachm of each to an ounce of starch, is applied. The part should be cleansed every night and morning, and the powder gently rubbed over the surface.

Fissure is another of the common and annoying troubles of this region. It is to be looked for when the patients complain of a burning, aching, or throbbing pain coming on during or within half an hour after an action of the bowels. The pain may last for only a few minutes to several hours. Frequently blood is lost in small amount. On examination, the part will be found contracted in appearance, and the patient is unable to force it down. Fissures are generally found in the middle line dorsally or anteriorly. The common advice for the treatment of this condition is to undertake at once some surgical measure, such as stretching or cutting. Dr. Goodsall, however, says that in mild cases the fissure may be cured by aperients, diet, and cleanliness. When the fissure is of long standing and there is some internal growth, the sphincter should be divided and the growth removed. In some cases of old-standing fissure the sphincter becomes hypertrophied and loses much of its natural elasticity; the fissure itself becomes somewhat cicatrized. In these cases the condition may be relieved by forcibly overstretching, and may be more certainly cured by complete division of the sphincter on one side only. Patients who will not submit to an operation will gain some relief by injecting an ounce of olive oil every night, this to be retained, if possible.

Venous piles are usually caused by straining or lifting heavy weights, and often come on suddenly. They cause pain and also itching and soreness and tenderness. Local applications of lead and opium, together with aperients, are usually sufficient to relieve this state, though in many cases a small operation is necessary.

For chancroidal ulcers, the writer recommends the application of a ten-per-cent. solution of cocaine, followed by the application of sulphate of copper.

THE INHERITANCE OF NEOPLASMS.

AMONG the questions which have interested medical men for ages there are few, perhaps, regarding which there has been more confusion of thought than that relating to heredity in its various bearings. At some time and in some form nearly everybody has regarded tuberculosis as hereditary, yet on occasion many who may have observed it desolate families have denied its heredity, for no other reason than that it does not accord with their conception of a beneficent Creator that innocent offspring should inherit disease from parents. Some men of high scientific attainments have sought to offer balm to an anxious public by proclaiming that cancer cannot be hereditary, since it is unreasonable that a disease which makes its appearance many years after birth should in reality date from intra-uterine life. But science has no regard for sentiment, and when an abnormality, a lesion, or a weak organ which furnishes a culture bed for disease germs is inherited, it simply notes the fact. It is the facts of the case which scientists would know.

Dr. Féré, of Paris, recently reported to the Société de Biologie a number of observations and experiments touching upon this question. He has found that the embryo of the chick between the twentieth and sixtieth hours may, if implanted under the skin of a chicken, grow and form a tumor with elements which had not been differentiated when the graft was made. After a time the tumor disappears by absorption. He says one can conclude from this experiment that embryonic elements remaining in tissues normally developed are capable of ulterior evolution. Thus, the theory of the embryonic origin of certain tumors and the teratologic theory of the heredity of tumors, and their family connection with diseases to which there is congenital predisposition, finds interesting support.

These experiments and others, consisting in interference with eggs in the brooder, showed that under nearly similar conditions there was considerable difference in the effect upon the nature of the tumor in the one case and upon the development of the chicken in the other. Féré also relates a few cases of asymmetrical development of one side in man, combined with other stigmata, such as tumors on the defective side of the body, pointing to a degenerate type, and concludes that the multiplicity of tumors in the same individual, their heredity, and the dissemblance in their heredity place them among the characteristics of degeneracy. Their accord with teratological deformities in the family and the individual is favorable to the hypothesis of a common origin of the degeneracies (neuropathies, arthropathies, etc.), with which tumors may also find themselves associated. Féré would apply the term *famille teratoplasique* to the non-parasitic group of tumors. In his experiments, he finds that agents capable of influencing the development of the embryo are not limited in their action to a retardation of development or to a production of malformations: briefly stated, they produce variation, which may be either exaltation or depression.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending October 3, 1896. September 28th.—Assistant Surgeon R. G. Brodrick detached from the *Franklin* and granted leave for two months. September 30th.—Medical Director W. K. Van Reyepen ordered to duty as member of the inspection and survey board, October 1st. Medical Inspector J. C. Wise detached from duty on the board of inspection and survey and ordered to museum of hygiene, October 1st.

Physician Shoots Druggist.—Dr. George S. Henry, of Duncannon, Pa., was shot and probably wounded fatally on September 28th by Dr. T. L. Johnston, who accused the former of immoral relations with the wife of the latter. Mental aberration is suspected on the part of Dr. Johnston, who has been a successful practitioner and at the time of the accident was acting president of the Duncannon National Bank.

The New President of the New York State Lunacy Commission, Dr. Peter M. Wise, entered upon the duties of his office on October 1st. He was appointed by Governor Morton to succeed Dr. Carlos F. MacDonald, resigned.

Prof. Rudolf Virchow will be seventy-five years old on the 13th of this month, and it is proposed in Berlin to celebrate his birthday in a worthy manner. He was born in Schivelbein, Pomerania, and obtained his medical degree at the University of Berlin in 1843. He was appointed physician to the Charité and Privatdocent to the university just fifty years ago.

The Deadly Chewing-Gum.—A young man who was scorching for a record on a bicycle track a few days ago was thrown from his wheel. When picked up his face was cyanotic and his arms and legs were twitching convulsively. A physician found a ball of chewing-gum, the size of a walnut, obstructing the entrance to the larynx. The gum was removed and the man recovered. In the interest of æsthetics it is to be hoped that this accident will serve as a warning, to wheelmen at least, if not to other men, to desist from their deforming habit.

Obituary Notes.—DR. WILLIAM REMSEN TAYLOR, of Long Island City, died at the home of his brother in Middletown, N. J., on October 1st, after a long illness. Dr. Taylor was health officer of the city for six years and was a candidate twice for the office of coroner and once for mayor on the Republican ticket. He was a graduate of the Long Island College Hospital in the class of 1864.—DR. CHARLES H. CHALKLEY, professor of chemistry, toxicology, and medical jurisprudence in the University College of Medicine, Richmond, Va., died on September 13th. He was born in Powhatan County, Va., August 4, 1859, and was a graduate of the Medical College of Virginia in 1883.—SIR WILLIAM JAMES MOORE, of London, died recently at the age of sixty-eight years. He served in

the Bombay medical service from 1852 to 1888. He was honorary surgeon to the viceroy of India, and after his retirement from the service and return to London was appointed honorary physician to the Queen.—DR. HENRY HOOPER MITCHELL died at Elkton, Md., on September 27th, at the age of seventy-seven years. He was a graduate of the University of Pennsylvania and began the practice of his profession at Elkton immediately after receiving his degree.

The French Congress of Alienists and Neurologists will meet at Toulouse in 1897. The following questions are proposed for discussion: 1. Differential diagnosis of general paralysis. 2. Infantile hysteria. 3. The medical service in lunatic asylums.

The Semi-Centennial of the Discovery of Anæsthesia is to be celebrated in Boston on October 16th, in the amphitheatre of the Massachusetts General Hospital. The following addresses will be made: "Address of Welcome," by Charles H. Dalton, Esq., president of the Massachusetts General Hospital; "Reminiscences of 1846," by Dr. R. T. Davis, of Fall River, and Dr. Washington Ayer, of San Francisco; "Surgery before Anæsthesia," by John Ashhurst, Jr., M.D., of Philadelphia; "What Anæsthesia has Done for Surgery," by David W. Cheever, M.D., of Boston; "Relation of Anæsthesia and Obstetrics," by John P. Reynolds, M.D., of Boston; "The Influence of Anæsthesia upon Medical Science," by W. H. Welch, M.D., of Baltimore; "The Surgery of the Future," by Charles McBurney, M.D., of New York; "The Birth and Death of Pain," a poem, by S. Weir Mitchell, M.D., of Philadelphia.

Dr. Samuel Fenwick has resigned his post as visiting physician to the London Hospital, after an incumbency as physician and assistant physician of twenty-eight years. He has been appointed to the consulting staff.

The Ninth Congress of Italian Alienists was held in Florence from October 5th to 9th.

Fraudulent Testimonials.—The British Medical Defence Union has taken up a case of the publication of a bogus testimonial in favor of a drug preparation. It appears that an American firm sent to English physicians a pamphlet describing the virtues of a new drug, and among the testimonials in the pamphlet was one to which was appended the name of a well-known physician. He knew nothing about the drug and had never used it, and naturally objected to the unwarranted use of his name.

Trained Nurses in California.—Many trained nurses from Philadelphia and Baltimore have recently been induced to go out to San Diego and other places in Southern California on the representation that they could find employment there that would pay them \$20 or \$25 a week. On arriving there, however, they have found that there was no work for them, and that, even if there were, they could not obtain any such remuneration for their services, and they have in many cases had to send to their friends in the East for money to enable them to return home. The San Diego Medical

Society recently adopted a preamble setting forth these facts, and a resolution stating, "for the information of such as may hereafter be likely to fall victims to such misrepresentation, that the profession of nursing is now greatly overstocked, and that at no time has any demand or such opportunities existed for trained nurses as represented."

The Medical Service in the British Army is rapidly deteriorating, owing to the snubbing which its members constantly receive from the commander-in-chief of the army and his subordinates among the so-called combatants. There are at present, it is said, about forty vacancies and no candidates can be found to fill them. The pay at some stations does not meet the medical officer's necessary expenses, but one of the most galling points in the situation, says the *Medical Press*, is the supercilious social attitude, for the most part, assumed by the combatant officers. The newly fledged army medical, who is, in nine cases out of ten, a man of liberal education and decent social position, finds himself the only medical man on a station. He is admitted, not as a right but upon sufferance, to the officers' mess, and is thus at once introduced to the system of arrogant social snobbishness with which the British army is still cursed, at any rate, so far as its medical branch is concerned. What wonder if the medical schools now warn all students against choosing the army as the scene of their future career? It will be interesting to observe what impression the dearth of candidates will have on the heads of the department.

"**The Edinburgh Medical Journal**," as we noted recently, has been bought by a new publisher and is to have a new editor. The change, however, does not appear to have given very general satisfaction. The sale was effected without notice to the editor or to the two medical societies of which the journal was the recognized organ. The members of these societies are now talking of organizing a syndicate among the physicians of Edinburgh to establish and conduct a new medical journal.

The Association of German Physicians and Scientists held its sixty-eighth annual meeting at Frankfort-on-Main, during the week ending September 28th. Among the general addresses delivered were essays by Dr. Buchner, of Munich, on "Biology and the Science of Health;" Dr. Below, of Berlin, on "The Practical Aims of Military Hygiene;" and Dr. Weigert, of Frankfort-on-Main, on "New Questions in Pathological Anatomy." A discussion on "The Results of Recent Investigations on the Brain" was participated in by Flechsig, of Leipzig; Edinger, of Frankfort; and von Bergmann, of Berlin.

The Government of South Australia is a queer thing. It recently turned out the medical staff of the Adelaide Hospital and, being unable to find subservient tools among the local profession, imported some London doctors to fill the vacancies. Now it has again shown its contempt for medical men by appointing a layman to the office of public vaccinator for the colony.

The Fourth French Medical Congress will be held in Montpellier in the spring of 1898, under the presidency of Professor Berrheim, of Nancy. The questions proposed for discussion are: 1. "The Clinical Forms of Pulmonary Tuberculosis." 2. "Microbic Associations and Mixed Infections." 3. "Therapeutic Use of Organs with Internal Secretion."

A New Uniform for Members of the Hospital Corps of the Army.—Upon the recommendation of the surgeon-general of the army, Secretary Lamont has directed a change in the army regulations in reference to the uniform of members of the hospital corps. In place of the regulation full-dress uniform of blue heretofore prescribed, members of the hospital corps will hereafter receive an allowance for an extra suit of white duck. Members of the corps are not required to turn out for parades and inspections of troops, and therefore it was deemed unnecessary that they be required to wear the full-dress uniform of the army. When these men are called upon for duty the service required of them is of a character that demands clothing that will be more comfortable and better adapted to their particular duties than that prescribed for the enlisted men of the army. A white duck suit in a hospital ward will not only prove more comfortable for the wearer, but the appearance will be more in keeping with the surroundings and the duties to be performed.—*College and Clinical Record*.

Dr. Charles A. Powers, of Denver, Col., while on a visit to this city, was the recipient of many courtesies from his numerous friends here. Dr. William T. Bull tendered him a complimentary dinner on Wednesday evening at the New York Club.

Beri-Beri has broken out again in the Richmond District Lunatic Asylum in Dublin, twenty cases of the disease being at present under treatment there. There was a similar epidemic in the same institution last year. The asylum is greatly overcrowded, and a hospital is soon to be erected at Portrane to relieve the congestion in the wards of the Richmond District Hospital.

Dr. George L. Peabody.—The many friends of Dr. Peabody in this city and elsewhere will be pleased to learn that he is now convalescent after the operation for appendicitis which was performed at his country place, Gaspé, Canada, by Dr. Sheppard. He is at present under the care of Dr. Sheppard at the Montreal General Hospital.

The Mount Vernon City Hospital was closed four weeks ago for want of funds, the aldermen having refused to make a sufficient monthly appropriation to meet the necessary running expenses. A man was shot in the town a few days ago and, as there was no place where he could be attended to, the coroner, Dr. A. T. Banning, took him into his own house. He had subsequently to be removed to Yonkers for operation and died, and now it is claimed that the man's life might have been saved could he have been operated upon without being moved such a distance. The murderer will probably profit by this when he comes to be tried for the shooting.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Ninth Annual Meeting, Held in Richmond, Va., September 22, 23, and 24, 1896.

THE association met at the Jefferson Hotel, and was called to order, at 10 A.M., by the president, DR. JOSEPH PRICE, of Philadelphia.

The Cause of Pelvic Disease.—DR. JOHN M. DUFF, of Pittsburg, read the first paper, which was entitled "Pelvic Diseases and Their Principal Causes: What Should the Laity be Taught Concerning Them?" He said that notwithstanding the fact that some of the prominent members of the medical profession had, in talks to the galleries, held the gynecologists up for ridicule and criticised them severely, he did not think any apology was due either the profession or the public for the character or results of the work of pelvic surgeons. Those members of the profession who had been devoting themselves to the care of diseases peculiar to women, had, in the face of revilings and professional and public prejudice, worked patiently and persistently, until they were now obtaining results of which they may well feel proud, results far beyond what the most sanguine expectations of the hardy pioneers of a quarter of a century ago led them to hope for. They were to-day charged with irrational radicalism, with an operative mania, which was gratified without a proper consideration of the ultimate benefit to the patient. Entreatingly they were urged to adopt more conservative measures, and thus stop the wholesale mutilation which was going on at present, which it is claimed is neither scientific nor humane. Sentiments such as these, endorsed by men of reputation, were eagerly taken up by the lay press as sensational news, and advertised by pretenders as an endorsement of their methods of practice; and thus the laity, in the opinion of Dr. Duff, is taught false notions regarding the nature of pelvic diseases and their treatment. That there is a great amount of mutilation connected with pelvic surgery, he would not deny; but that regular pelvic surgeons were guilty of reckless despoliation was not, he thought, susceptible of proof. Pelvic surgeons could scarcely be held accountable for the work of general practitioners; and for the work of ignorant egotists and pretenders, who with brazen effrontery undertake operations for the performance of which they are not qualified by character, experience, or education, the pelvic surgeons disclaim all responsibility. During the period of the evolution and upbuilding of pelvic surgery, no doubt much of the work was crude, and perhaps too much was done by overzealous operators. That at this day, through mistaken diagnosis, operations are sometimes needlessly performed, no one would have the hardihood to deny; but that such cases are as frequent as some critics say they are, Dr. Duff could not believe. He said the true pelvic surgeon was governed by nobler purposes, by more elevated aims. Conservatism in its true sense—the saving of life, relief from pain, the curing of the patient—was his watchword.

Deceptive Similarity of Signs and Symptoms of Intra-Abdominal Disease, with Cases.—DR. WALTER B. DORSETT, of St. Louis, followed with a paper on this subject. In order to arrive at a conclusion and to formulate a diagnosis in a given case, be it medical or surgical, the practitioner must exercise care and judgment in the consideration of such signs and symptoms as are presented. Each should be weighed, and mental annotations taken as to their value individually and collectively. Dr. Dorsett directed at-

tention to the importance of the family and personal history and habits of patients, to the pulse and temperature, the knowledge to be gained by manual examination, the use of analgesics, etc. Regarding the exploratory incision, it should not be regarded as an evidence of ignorance, but as a legitimate means of diagnosis, and the off-hand diagnostician or the surgeon who never makes mistakes should be looked upon with at least a grain of suspicion. To illustrate his statements, he reported the following case:

Mrs. M—, aged twenty-eight, married eight years, no pregnancies, was seen by Dr. Dorsett about a week after having recovered from an attack of malarial fever. Temperature, 99° F.; pulse, 90; tongue slightly coated, and a tendency toward diarrhoea. Complained of general abdominal tenderness. Palpation of abdomen revealed a slightly more tender spot at McBurney's point; no swelling or tumefaction could be felt. A vaginal examination revealed a retroversion with fixation; no tubal enlargement nor tenderness could be made out, and no vaginal discharge. Diagnosis: Gastro-intestinal irritation, with chronic inflammation of pelvic contents. Diarrhoeal mixture was prescribed, and patient was told that further attendance would probably not be necessary. Four days subsequently the temperature was 99.8° F.; pulse, 100. Abdominal palpation revealed a distinctly tender spot with some swelling at McBurney's point. Patient stated that she had eaten heartily of Wienerwurst the day before, and had been awakened during the night by cramps at the navel. Bimanual examination was again resorted to, with negative result. Appendicitis was diagnosed at this visit, first stage. Drachm doses of salts were prescribed, and patient was urged to go to the hospital, but refused. The next day she was found sitting in a rocking-chair, and, aside from slight tenderness over abdomen, was feeling quite comfortable. The salts had acted freely. Bimanual examination again gave negative results. Temperature, 99° F.; pulse, 100. Patient was ordered to bed and advised to keep quiet. At that time she was regarded as better, and thought to be out of danger, but the following day the pain became more severe, and the patient came to the hospital of her own accord. Upon examination the right iliac fossa was found to be exceedingly tender and fluctuating. Vaginal examination revealed nothing aside from what was found at the previous examination. Temperature, 103° F.; pulse, 130. Diagnosis: Ruptured appendiceal abscess. She was anesthetized and placed upon the table, and a section made in the median line. The large sac was found on the right side filled with fluid blood and clots, and when washed out a rent of the posterior layer of the broad ligament was found, which communicated with another rent in the Fallopian tube. The appendix was perfectly healthy and was not disturbed. A thorough washing out of the sac was done and ligation of the tube with a portion of the broad ligament; a glass drainage tube was introduced. Notwithstanding the utmost care, the temperature remained high, the pulse became worse, the abdomen became distended, and the patient died on the third day. Post-operative diagnosis: Ruptured tubal pregnancy, without the usual symptoms. There were no history of shock, no cessation of menstruation nor any nervous symptoms of pregnancy, no passage of decidua, no vaginal discharge of any kind; but in their stead a good history and train of signs and symptoms of inflammatory disease of the appendix.

The Most Potent Causes of Pelvic Inflammation.—DR. RUFUS B. HALL, of Cincinnati, read this paper. He claimed that septic infection following labor or abortion, or gonorrhoeal infection, was the cause in almost every instance. He said there would always

be some cases of septic infection following labor, which are in no wise due to infection from the attendant, injury to small pelvic tumors, etc. The retention of the products of conception in abortion is a very frequent cause. He advised complete emptying of the uterus at once after abortion. He believed the most frequent cause to be gonorrhœal infection conveyed to the woman from a latent gonorrhœa of her husband. The more he saw of the ravages of gonorrhœa, the more he was convinced of the fact that physicians are derelict in their duty to their patients in the dissemination of knowledge upon this subject. The teaching of a few years ago that gonorrhœa in the male could be easily and speedily cured by a little balsam of copaiba or oil of sandal wood, with mild astringent injections, and that the patient was well as soon as the purulent discharge ceased, is false doctrine and must be corrected. This must be done by the family physician. Dr. Hall said that on many occasions he had been compelled to remove suppurating tubes and ovaries from women who had contracted the disease from husbands who believed themselves well when married. He had no hesitation in saying that gonorrhœa is more destructive to women than syphilis, and believed it is the duty of every physician to impress upon his male patient the fact that he is not well as soon as the urethral discharge disappears. He was a firm advocate of legislation upon this subject, believing that every man should have a certificate from the health officer of freedom from syphilis and gonorrhœa before he could obtain a marriage license.

DR. J. HENRY CARSTENS, of Detroit, in discussing Dr. Dorsett's paper, said that the difficulty attending diagnosis in some cases was exceedingly great. The gynecologist should exhaust his diagnostic resources before resorting to abdominal section. The too frequent opening of the abdomen stimulated incompetents to do likewise, and as a consequence results were disastrous, eventually reacting on gynecologists.

DR. W. E. B. DAVIS, of Birmingham, Ala., did not believe that gonorrhœa played so important a part in the production of pelvic inflammation as had been asserted. One's conception of causes of pelvic trouble depends largely upon the class of patients one has. The cases met with in dispensary practice are different from those encountered in private practice. He believed that fully fifty per cent. of the cases of pelvic inflammation are due to puerperal infection, either at the time of delivery at full term or of premature delivery. As to tuberculous trouble, more importance is being attached to it as a cause of pelvic inflammation than it deserves. Those who did considerable operative work knew that only a small percentage of cases have their origin in tuberculosis.

DR. JAMES MACFADDEN GASTON, of Atlanta, called attention to the prophylactic management of cases of pregnancy prior to the period of confinement. Extreme hygienic precautions might warrant in some instances the use of antiseptic douches prior to labor, but there was a great tendency on the part of some members of the profession to resort to measures which are regarded as precautionary, and to order douches in advance of confinement. He believed that this was altogether out of place, for when there is a normal condition of things nature should be allowed to take its course.

DR. ERNEST S. LEWIS, of New Orleans, cited a case illustrating the errors that sometimes arise in the diagnosis of abdominal tumors. He operated on a patient last winter for what he supposed at the time was a small ovarian tumor, but after the abdomen was opened it turned out to be a retroverted gravid uterus.

Tubo-Ovarian Cysts.—DR. ALBERT GOLDSPOHN, of

Chicago, read a paper on this subject. By tubo-ovarian cyst is meant a non-purulent sac whose walls are composed, in variable proportion, of the walls of the Fallopian tube and those of some cystic ovarian or parovarian formation, with the coalescence of two or more cavities—at least one from each—into one, by a free communication. The fluid contents of such a sac may be serous or hemorrhagic, or may partake, in variable degree, of the qualities and characteristics of the fluid contained in glandular ovarian cystomas. The fimbriae of the abdominal ostium of the tube may be distinguished or not upon the inner or on the outer side of the ovarian portion of the sac, or they may have coalesced with other structures to form some portion of the walls of the united sac. The ovarian element in this formation can have originated from a hydropic Graafian follicle, a cystic corpus luteum, from the primordial glandular ducts of Pflueger in the ovary, or from the parovarian. In order to exclude a large number of ordinary tubo-ovarian conglomerates, we need to recognize the following minimum requirements in distinguishing a tubo-ovarian cyst: (1) The participation of the tube, which is easy enough from its position and connections. (2) To prove the participation of the ovary by demonstrating some ovarian tissues in the wall of the sac. (3) That their cavities are united by some opening through which the mucous membrane of the tube is continuous with the lining of the ovarian cyst or follicle. The following were the conclusions of the paper: 1. Tubo-ovarian cysts come to pass in consequence of a plastic inflammatory union between a Fallopian tube and the adjacent ovary, after either or both of these organs and the intervening peritoneum have experienced a non-purulent pathological change of a cystic character, the septum intervening between the two lumina disappearing in consequence of pressure atrophy from the tension of liquid confined to one or both sides of it. 2. This union of a distended tube cavity may occur also with that of a parovarian cyst (v. Ott) or with that of a peritoneal pseudo-cyst (Zedel). 3. In those rarer cases in which the fimbriae are really found floating in the interior of the main cyst cavity, we must assume either the congenital anomaly of an "ovarian tube," as was seen by Schneidmahl in a mare, as a *ritum primæ formationis*, or that an ovarian cyst or follicle cyst ruptured, and the abdominal end of the tube dropped into the rent and was united to its edges by inflammatory action, thus making a joint cyst and tubal cavity.

Mixed Tumors of the Ovary.—DR. WALTER B. CHASE, of Brooklyn, followed with a paper with this title. Mixed tumors of the ovary have a peculiar interest, for the reason that, if small, they are often difficult of diagnosis. These tumors of the ovary may be made up of a variety of cysts, or may be a combination of cysts and solid growths. The etiology of tumors as a whole is a matter of great importance, both in the relation to diagnosis and treatment. The question of what constitutes a tumor might be considered with profit. Senn defines a tumor as "a localized increase of tissue proliferation of embryonic cells of congenital or post-natal origin." An important fact concerning true tumors is that they never disappear except by removal or destruction. Benign tumors always remain local, while malignant ones are disseminated by migration or transportation of their peculiar cells, and they always originate as benign or malignant growths. If the tumor matrix is made up of embryonic cells of the lowest development, there is greater liability to malignant growth than if from tissues susceptible to the highest physiological type of development. Retention cysts of the ovary are not tumors in a technical sense, and they never attain large size. Large ovarian cysts are most often cystadenomas and are not developed from Graafian folli-

cles, but arise from the embryonic structure. It would seem then that the genesis of simple and mixed tumors is divested of much that is misleading and contradictory and reduced to a rational basis. It also demonstrates with great clearness that tumors are not only of local origin, but at their inception are congenital.

Movable Kidney: Local and Remote Results.—DR. A. H. CORDIER, of Kansas City, Mo., read a paper on this subject, in which he drew the following deductions: 1. A movable kidney often produces a dilatation of the stomach with all the accompanying symptoms of a disease of that organ. 2. It is a fruitful source of gall stones, because of the pedicle producing a partial obstruction of the common duct. 3. The bending of the ureter often gives rise to a hydronephrosis. This, in turn, is sometimes converted into a pyonephrosis. 4. It may produce death by a complete strangulation by a torsion of the vessels and ureter. 5. By dragging on the abdominal aorta and kinking the vena cava, a condition simulating an aneurism of these vessels may be produced. 6. Pain of a referred character to the region of distribution of the spinal nerves is often induced by a movable kidney's disturbance of the abdominal brain. 7. A general nerve exhaustion (neurasthenia) is often induced by the interference of this condition with digestion, assimilation, and elimination. 8. Nephrorrhaphy is a safe and effective surgical procedure. 9. All cases of movable kidney, if accompanied by symptoms pointing to the kidney as their source, should be operated on. 10. In summing up the local and remote results of this now often recognized condition, the author thinks the correctness of the deductions has been frequently demonstrated by the disappearance of each and every symptom after a restoration and retention of the kidney in its normal position. 11. Symptoms are not to be relied upon in making a diagnosis of movable kidney. The physical examination is the only trustworthy guide.

The Limits of Nephrorrhaphy was the subject of a paper by DR. HUGH M. TAYLOR, of Richmond, Va. He conceded the frequency of nephroptosis. Since he had been systematically looking for movable kidney, he had found it so frequent in its occurrence that he no longer regarded the experience of Glénard, Lindner, Edebohl, and Noble as unique. His opinion was equally fixed that only a small proportion of the cases met with give rise to symptoms of suffering, ill-health, or death, and consequently a majority of cases do not call for nephrorrhaphy. He favored the classification of nephroptosis under three clinical heads: 1. Patients who have displaced kidney, do not know it, and suffer no inconvenience whatever from it. This type he thinks represents by far the largest class. 2. Patients with displaced kidney, who may or may not know it, who suffer from gastro-enteric discomfort and perhaps a long train of vague neurotic disturbances. In this type he thinks we find the largest class calling for operative interference. 3. Patients with movable kidney who are subjects of occasional or frequent mild or severe attacks of renal crises. This last mentioned is, he thinks, the least frequent type met with, but the urgency of the symptoms more frequently demands operative interference. Nephrorrhaphy for the relief of gastro-enteric disorder is limited by our ability to tell to what extent the disorder is due to renal ptosis *per se* or to enteroptosis, or to some one of the many well-known etiological factors of gastro-enteric disorder. Nephrorrhaphy for the relief of the condition of Deitl's or renal crises must be limited by one's success in differentiating between this condition and that of gall-tract, appendicular, and kidney colic due to nephrolithiasis. He accepted as logically sustained the conclusion that the

Deitl's or renal crisis is due to a kink or twist of the ureter with retained urine in the ureter and pelvis of the kidney. Apart from the violent paroxysms of pain (the renal crisis), the tendency of ureteral twist and urinary obstruction to induce hydronephrosis and in exceptional instances pyonephrosis rendered operative interference more imperative in this class of cases. His protest was not against nephrorrhaphy, but against its abuse. He conceded the value of operative interference in many selected cases, but deprecated the tendency toward operative interference merely because the kidney is movable.

DR. GEORGE BEN JOHNSTON, of Richmond, Va., said that some years ago his attention was called to the subject by encountering several cases of movable kidney that had been unobserved either by him or by the physician who preceded him in the treatment of these cases for obscure nervous and gastro-intestinal disturbances, and when he observed the similarity of symptoms in the first three cases which he saw he was obliged to associate those symptoms with the presence of movable kidney. He prevailed on these women to be operated upon for movable kidney and in all three cases the results were most gratifying.

DR. L. H. DUNNING, of Indianapolis, was greatly interested in the subject, for the reason that about 1880 he resorted to operative procedures for the cure of floating kidney, and in connection with this work he sought to determine if possible some of the causes which led to movable kidney. He emphasized the importance of differentiating between floating and movable kidney, the former being always congenital, the latter acquired to a greater or less extent. He found by his investigations that the partially fixed condition of the kidney depended upon three or four causes, the two principal ones of which were its position behind the peritoneum and the fact that it had an envelope of cellulo-adipose tissue. A little further investigation showed that the perinephric cellulo-adipose tissue was composed of two parts, one fixed, the other movable. The normal kidney had a range of motion of from one-half to three-quarters of an inch in its fatty envelope.

DR. THOMAS B. EASTMAN, of Indianapolis, reported the case of a woman, twenty-five years of age, who came to him with the symptoms of appendicitis. She also had considerable albumin in the urine. Operation showed that the appendix was firmly adherent to the kidney. It required considerable force to liberate it. As soon as liberated the kidney bounded back into place as though it were rubber. The appendix was removed, the albumin in the urine ceased, and the woman made an uneventful recovery.

DR. JAMES MACFADDEN GASTON, of Atlanta, directed attention to the possibility of movable kidney being mistaken for enlarged gall bladder. The gall bladder was capable of being pushed back into the lumbar region and carried around in front in just the same manner as a floating kidney. It behooved gynecologists to look into this phase of the matter.

DR. W. E. B. DAVIS, of Birmingham, had seen a number of cases of movable kidney, and said that at the Charleston meeting of the Southern Surgical and Gynecological Association there was quite a difference of opinion as to the frequency of the condition. He believed that movable kidney was a condition which did not require in all cases operative interference. Of the number of cases he had seen he had only operated on a few.

DR. I. S. STONE, of Washington, D. C., related the case of a woman who, after the operation of nephrorrhaphy had been performed, gained twenty-five pounds in flesh. In many instances this procedure brought color back to the cheeks of patients and made them feel well. He had never seen such gratifying

results from any other operation in surgery, except, perhaps, the removal of an ovarian tumor. The patients made rapid improvement after the operation.

DR. JOSEPH PRICE, of Philadelphia, said his experience was somewhat limited in operating for movable kidney. The improvement in the condition of patients so operated upon was rapid, but there was such a thing as operating too much upon cases of movable kidney.

DR. J. HENRY CARSTENS, of Detroit, said the line should be drawn between movable and floating kidney. The trouble which arose from floating kidney consisted of a twisting of the ureter and consequent obstruction.

Treatment of Peri-Uterine Septic Diseases.—DR. W. E. B. DAVIS, of Birmingham, Ala., read a paper on this subject. Only recently has the extremely radical procedure of hysterectomy been practised in this country for septic diseases of the internal genitals. A wave which had its origin in Paris at the hands of Péan, aided by Richelot, Segond, Jacobs, and others, reached our shores three years ago and has found a considerable following among our leading operators. The claim is made that there is no use in leaving the uterus behind after the removal of the appendages. In every operation for septic diseases of the female generative organs which demands the removal of the tubes and ovaries, hysterectomy should also be performed, unless there are plain contraindications forbidding it. It should be the aim of the surgeon to preserve everything consistent with thorough surgical work, and not to sacrifice important organs because it can be done with only a small mortality. We are told that the uterus has no function after the removal of the appendages, but this has not been demonstrated; and, on the contrary, we know that the sexual life of the woman is very much better preserved by leaving the uterus, and that the mental effect is also much better. A slow convalescence, or even a second operation, is preferable to its removal, unless very much diseased. It is a reflection on the correctness of the reports by many most excellent surgeons of complete recoveries of such a large per cent. of the cases when the uterus was not removed, to accept the argument now being used in favor of hysterectomy in all these cases. As stated by Dr. Davis at the last meeting of the American Medical Association, he could not agree with Dr. Sutton and others that pus in the tubes was due to gonorrhœa in seventy-five per cent. of cases. He thought that puerperal infection was the cause of more than fifty per cent. Tuberculous infection was rarely the cause, and was not so important as had been claimed. However, the importance attached to gonorrhœa was against the argument for the removal of the uterus, as the infection from this source was not deep and could be removed with the curette. Because some patients were not completely cured by the removal of the appendages was no argument for hysterectomy in every case in which the bilateral operation was required; for nearly all these could be relieved by a thorough curettage. Some large uteri would require, in addition to this, a high amputation of the cervix, and only a small number would need a hysterectomy. Vaginal incision for the drainage of pus in the pelvis, not confined to the tubes, was a most valuable method of treatment in a well-recognized class of cases, and had been practised for a long time, with gratifying results. A large number of these cases required no further surgery. More recently large pus tubes and ovarian abscesses had been incised and drained through the vagina, with permanent recoveries in a good proportion of cases. The uterus should always be curetted at the same time. These were the very cases in which the vaginal operation and hysterectomy had been recommended so highly by the French surgeons. Yet a considerable percentage of these cases

could be relieved by vaginal incision and drainage. The object of the surgeon should be, not so much to reduce still further the death rate from the operation, but to relieve the subjects and preserve as far as possible organs which had so much to do with the woman's health and happiness.

Hysterectomy in the Presence of Active Inflammation.—DR. L. H. DUNNING, of Indianapolis, followed with a paper upon "Hysterectomy in Inflammatory Diseases of the Pelvic Organs." The author discussed only that form of inflammation of the pelvic organs and tissues denominated diffuse pelvic inflammation, and drew the following conclusions:

1. We recognize the utility of hysterectomy in a small percentage of cases of bilateral suppuration of the tubes and ovaries, in which the uterus is distinctly septic, and in cases of septic uteri which cannot be cured by other means after bilateral salpingo-oöphorectomy.

2. We oppose hysterectomy, as a rule, in inflammatory diseases of the pelvic tissues upon the following grounds; viz.: (a) The uterus is the central organ of the reproductive system, and should not, except upon palpable and urgent cause, be extirpated; (b) it is only in rare cases that the uterus is so far diseased as to resist the curative effects of appropriate treatment; (c) the removal of the uterus profoundly affects the nervous system and emotional nature of young women deprived of this organ; (d) we oppose the removal of the uterus from anatomical reasons; to wit: as a result, the vagina is shortened; the anatomical relations of the bladder, sigmoid, and rectum are changed; the elasticity of the pelvic diaphragm is greatly diminished or entirely removed, the elastic tissue being largely replaced by sensitive scar tissues; (e) in married women it often disturbs the sexual relations of husband and wife, and is apt to induce mental depression; (f) vaginal hysterectomy compels the use of drainage, because of the necrosis of tissue and suppuration induced.

Shall the Uterus be Left in Situ in Excision of the Adnexa?—DR. E. F. FISH, of Milwaukee, Wis., read a paper which was an argument in favor of leaving the uterus *in situ*, if sound, after excision of the appendages. It considered the pathological conditions requiring hysterectomy after salpingo-oöphorectomy, as well as the conditions which do not require it. The author argued against all operations which leave a degenerated uterus, such as Hegar's, Tait's, Martin's, and Robinson's, except under extreme conditions, and concluded as follows: 1. Whenever it becomes necessary to excise the uterine adnexa, if the uterus is sound, leave it. 2. Whenever we excise the tubes and ovaries, and the uterus, though in a pathological condition, in our judgment will yield to treatment, leave it. 3. Whenever it is necessary to do an abdominal hystero-salpingo-oöphorectomy and the cervix is healthy, do a supravaginal amputation, as this leaves the vaginal vault intact. 4. Whenever it is necessary to do a supravaginal amputation, suspend the cervix to the stumps of the broad ligaments or anchor it to the abdominal wall, to prevent prolapsus vagina. 5. Whenever it is necessary to do a general ablation, and the cervix uteri is unsound, take the entire organ, because of the danger of carcinoma. 6. Whenever a subserous or interstitial myoma can be removed without too great damage to the uterus, do a myomectomy and leave the organ. 7. Whenever we excise the appendages and leave the uterus, ventral fixation is not an unsurgical operative conclusion.

The author's reasons for leaving the uterus were that it helps to maintain the woman's sexual integrity: it relieves the patient of much mental strain, and is a prophylactic measure to neurasthenia, melancholia,

and insanity; it tends to maintain the family ties unstrained: it obviates the possibility of vaginal hernia, cystocele, and proctocele, and delays vaginal atrophy; and, finally, it holds up and prevents shortening of the vagina.

Dynamic Ileus.—DR. J. W. LONG, of Richmond, Va., contributed a paper with this title. Intestinal obstruction had been variously classified, but Dr. Long regarded the classification adopted by Murphy as the simplest and the most rational: 1. Adynamic ileus, always the result of intestinal paralysis, due to varying causes, may be clearly illustrated by such cases as those following injury to the spinal cord and paralysis due to peritonitis. 2. Dynamic ileus. This variety formed the subject of the paper, and was discussed in detail. 3. Mechanical ileus embraced such common lesions as strangulated hernia, intussusception, fecal impaction, etc. The speaker reported the following case:

Mrs. C—, twenty-one years old, married three years, but never pregnant; was rather below the medium size and height. In temperament she was of the spoiled-child type, not hysterical but rebellious. It was with great difficulty that she could be induced to have any local treatment or even to take medicines. After admission to hospital her obstreperous disposition required all the tact and firmness of a sagacious nurse. Early in April of this year the patient had malaria, followed by delayed menstruation, pelveo-abdominal pain, and obstinate constipation. The malaria and menstrual disturbance yielded promptly to treatment, but the abdominal pain continued, and gradually the ileus symptoms became more and more pronounced. After exhausting every other measure to move the bowels, the patient was put under the influence of chloroform, and by means of a Ricketts tube a quantity of fecal matter was washed away. Notwithstanding, there was no improvement, the nausea and vomiting recurred oftener and were more distressing, the pain and tenderness became worse, and a marked degree of tympany supervened. When she was brought to the hospital there had been no movement of the bowels for four weeks, excepting what was washed away with the colon tube while the patient was anesthetized. The history justified the diagnosis of intestinal obstruction, while the urgent symptoms demanded an immediate operation. The abdomen was opened by a median incision. No mechanical obstruction could be found, although a careful search was made along the whole length of the intestine. The bowel was moderately distended with gas and congested. A singular feature, however, was that at three points—two in the ileum and one in the sigmoid flexure—the canal was constricted sufficiently to constitute obstruction. In the ileum one of the constrictions was about fifteen inches from its lower end and six inches long; the other was nearer the jejunum and about four inches long. The lumen was not entirely closed at either point, but was greatly reduced, being less than half the normal size; while the diameter of the remaining portions of the bowel was increased, on account of the distention with gas. No peristalsis was observed, but the contracted portions could be dilated by “milking” the intestinal contents along. In the sigmoid the limitations of the contracted portion were not so sharply defined, but the lesion was just as evident. The walls were thickened and the calibre much diminished. Incidentally a small ovarian cyst on the right side was discovered and removed. As the intestine had been handled a good deal, the abdomen was flushed with normal salt solution. The incision was closed with two tiers of sutures—silk for the peritoneum and interrupted silver wire for the remaining layers. The recovery was most satisfactory in every way. The bowels responded

to the usual laxatives and enemas on the second day, and from the first to last there was not a hitch in her convalescence. The patient left the hospital in four weeks, and three weeks thereafter took a trip to Alabama. There could be discovered no evidence of lead or ptomain poisoning.

Spontaneous Rupture of the Uterus during Labor at Term.—DR. B. M. HYPES, of St. Louis, read a paper on this subject. Mrs. O—, aged thirty-one, of German parentage, general health good; had had one child four years ago. Labor pains began September 16, 1895, at 10 P.M., at full term. The family physician was called, and found labor in progress, vertex presentation, with normal condition of mother and child. The pains were slight and progress was slow. At 2 A.M., September 17th, he gave a dose of morphine and went home. At 9 A.M., upon his return, he found the patient comfortable, with occasional slight labor pains. He left the house, with injunction to call him when signs of labor became pronounced. Patient remained quiet during the day. Suddenly, at 3 P.M., she was seized with violent vomiting, followed by the most excruciating pains in her abdomen, associated with rolling and tossing in bed, gasping for breath, faint feelings, pallid face, and rapid exhaustion: in short, the usual symptoms of abdominal shock. The family physician was at once sent for, and upon his arrival, at 4 P.M., found her in complete collapse, with convulsive seizures. The symptoms, with vaginal and abdominal examination, revealed to him this dreadful condition: The presenting part receded, the womb empty, and the child plainly felt in the abdominal cavity. The patient had suffered spontaneous rupture of the uterus. The physician at once sent for surgical aid; but by the time the surgeon, Dr. Meisenbach, arrived, the patient was moribund. Still, with the hope of saving the child, laparotomy was hastily performed: and the child, which had escaped entirely into the abdominal cavity, was extracted from a mass of blood and amniotic fluid. It had ceased to live, and continued efforts at resuscitation failed to cause it to breathe. The child was fully developed, male, weighed six pounds, and was eighteen inches long. The uterus, when removed from the body, presented the following condition: A rupture through the fundus superiorly, extending from half an inch from the entrance of one tube to an equal distance from the entrance of the other: the walls at the place of rupture were comparatively thin. The placenta was located at the middle third of the uterus, anteriorly and to the right, where the walls were much thickened. The vaginal portion of the cervix was almost obliterated, as at term, and dilated for the ready admission of two fingers. The lower zone of the uterus exhibited no thinning or formation of Bandl's contraction ring; there was no disease of tubes, ovaries, or placenta. A microscopic examination was made soon after rupture, and revealed fatty degeneration of tissue at the point of rupture.

Porro's Operation.—DR. EDWIN RICKETTS, of Cincinnati, O., reported a case of “Porro's Operation at or near the Fifth Month for Small Fibroid of Cervix, Accompanied by Hydramnios and Total Retention of Urine.” Mrs. M—, white, aged twenty-six, of short stature; the mother of two children, of six and three years of age; had had an abortion at eight weeks early in 1895; there was no specific history. She was a patient of Drs. J. B. and C. M. Warwick, of Lucasville, O. On February 23, 1896, she had severe labor pains, lasting thirty-six hours and accompanied by slight hemorrhage. The right portion of the cervix was soft and the left hard, which condition was also present at the time of operation. During April and until May 22d, the date of operation, she had great tenderness over the lower part of the abdomen, and at

times had a temperature above 100° F., with a pulse running from 90 to 100. Dr. Ricketts saw her in consultation at her home, April 8, 1896, when for the first time motion of the fœtus was barely perceptible. On May 22d, Drs. Warwick, Kline, Sellards, and Ricketts found her abdomen larger than it should be at full term, which was due to the hydramnios present. There was no difficulty in moving the fœtus freely in the abdominal cavity, so thin was the uterine wall. It was considered unwise to delay surgical interference, and a Porro operation was therefore performed, under as strict asepsis as the circumstances would permit.

After the abdomen was opened, Dr. Ricketts passed his hand down into the pelvis, breaking up the pelvic adhesions. Upon the delivery of the fundus of the impregnated uterus through the abdominal incision, a rubber ligature was thrown around it, low down and tight enough to control any hemorrhage which might occur. The fluid which escaped, upon opening the uterus, surpassed in amount any he had seen delivered *per viam naturalis*. After carefully sponging the parts, the wire was tightly adjusted below the rubber ligature by means of the Koeberlé clamp, and the rubber ligature then removed. After the delivery of the placenta, the fundus was amputated, leaving the ovaries and tubes intact. The abdominal wound was closed with silkworm-gut sutures, without stitching any tissue to the stump below the wire. No drainage tube was used. The extraperitoneal part of the stump was dressed with gauze, moistened in glycerin and tincture of iron, the stump being held up by the double-hooded pin of Tait. The placenta and fœtus were small for one of nearly five months' gestation, and the cord was tied in almost a hard knot—harder than any he had seen. The fœtus had marked cyanosis and gasped but once. Recovery of the mother was satisfactory.

Treatment of Puerperal Infection.—DR. H. W. LONGYEAR, of Detroit, first spoke of the prophylaxis and, under this head, of the difficulty of securing reliable statistics regarding puerperal mortality of patients under the care of midwives in this country. The prophylaxis was divided into general and specific. He spoke of the treatment of infection from abortion and from childbirth at full term, and presented an instrument designed by him for use in removing the remains of secundines from the uterus. He also exhibited a self-retaining drainage tube of his own invention and demonstrated its applicability. He reported two cases of puerperal infection treated successfully by the use of diphtheria antitoxin serum. He condemned the performing of hysterectomy for puerperal septicæmia except in very exceptional cases.

Atresia with Retention of the Menses; Treatment.—DR. WILLIAM G. MEYERS, of Fort Wayne, Ind., read a paper with this title. The author reported two cases of atresia, one with absence of the vagina and uterus, and the other with retained menstrual fluid. The last was operated upon successfully. He believes that in a case of atresia of the vagina with retention of menstrual fluid in the uterus, an operation ought to be completed at one sitting, the direct method being adopted. He thinks the teaching in a recent work, that "the best way is to make a small opening into the mass and allow the contents to flow away gradually," is not sound. He could not therefore see in rapid evacuation such great dangers as were referred to in the books.

Principles and Progress in Gynecology.—DR. JOSEPH PRICE, of Philadelphia, delivered the president's address. He first thanked the association for the distinguished honor conferred in electing him president, which he said was the most gratifying expression of personal and professional kindness. He said the association was made up of earnest, enthusiastic, and

eminent men of the medical profession. We had more than a passing interest in the record of the transactions of our medical and surgical associations. From them the history of the progress of medical and surgical science would be made up; they would reflect the advanced thought and opinions, the strength of the endeavors, the results of clinical experience and research of the profession of this period. We had the inspiration of the reflection that our high service was that of humanity, and, Dr. Price said, the members were there to learn through the interchange of the best counsel how to make that service the best.

Some Causes of Insanity in Women.—DR. GEORGE H. ROHÉ, of Sykesville, Md., read this paper, of which the following is an abstract: The general causes of insanity are the same in women as in men, but there are modifying conditions in the life history of men and women that influence the causation of mental disturbance as between the two sexes. General paresis and alcoholic insanity are more frequent in men because the latter are exposed to their causes to a greater degree and intensity. Menstrual, puerperal, and climacteric insanity are on the other hand self-evidently limited to women. Women are especially subject to mental disturbances, dependent upon their sexual nature at three different periods of life: puberty, the child-bearing period, and the menopause. The functions and activities peculiar to these periods have an intimate etiological relation to certain insanities. It is probable, however, that these functions have no influence in the production of insanity in their normal condition. It is only when the functions are disturbed or when pathological conditions are present that they have any unfavorable influence upon the psychological functions. At the period of puberty, menstrual derangements are not infrequently causative of mental disturbances which do not yield until the menstruation becomes normal. In the puerperium, insanity is dependent upon septic absorption or upon the consequences of other morbid conditions of the reproductive organs. Lactational insanity may be due to physical exhaustion, but in some cases pathological conditions of the genitals or of the breasts seem to have an etiological relation. At the menopause the disturbances of nutrition associated with the arrest of menstruation often produce insanity, and in many of these cases there will also be found abnormal alterations of the reproductive organs. The insanities following gynecological operations are either due to septic conditions, or are merely due to the rapidly induced menopause. Their frequency has been much exaggerated.

The Relation of Visceral Disorders to the Delusions of the Insane.—DR. WALTER P. MANTON, of Detroit, Mich., said that the delusions of the insane are often an expression of somatic peripheral irritation has long been recognized, but observation leads Dr. Manton to believe that the importance of these mental manifestations as indices of bodily suffering was frequently ignored and they were regarded as a mere phase of the brain disorder, especially in the instance of supposed fancied visceral disturbances. For convenience of consideration, he placed the so-called visceral lesions in four classes: 1. Delusions arising *de novo* from the diseased activity of the brain. 2. Delusions regarding external or visible abnormal bodily conditions. 3. Delusions arising from easily determined visceral disorders. 4. Delusions dependent upon obscure abdominal and pelvic states.

Oöphorectomy for the Insanity and Epilepsy of the Female.—DR. DAVID T. GILLIAM, of Columbus, O., contended in this paper that oöphorectomy was a logical and legitimate operation for the epilepsy and insanity of the female. Insanity is hereditary, as is also epilepsy. They constitute the greatest curse to hu-

manity. An insane father or an insane mother brings more misery into the world than any other father or mother. The offspring of such a parent, when ushered into the world, would be confronted by the awful spectre of impending doom, and though he called on the rocks or the mountains to fall on him, the curse would pursue and overtake him. Dr. Gilliam then gave a picture from real life. He would limit the operation to those in whom the malady appears in some way to be connected with or dependent on sexual disturbance. He would go further and include all who were willing to undergo the operation to save themselves and their offspring from the miseries which awaited them.

Treatment of the Stump to Prevent Adhesions.

—DR. J. F. BALDWIN, of Columbus, O., followed with a paper on this subject. He estimated that about one per cent. of all subjects operated upon die from intestinal obstruction, the result of adhesions to the stump. To diminish as much as possible the danger of adhesions he recommended the careful closing in of stumps by a peritoneal flap, and described the method of securing this flap. In cases in which the pedicle is, after a simple ovariectomy, not too large, he recommended that the pedicle be so ligated that the ends of the ligature were on the anterior face of the pedicle; that the ends of the ligature be then carried across the face of the stump, down and through the broad ligament, transfixing the ligament from behind forward. The ligatures should be passed through about half an inch apart. As the ends were drawn through and tightened, the raw end of the stump should be rolled down and under the broad ligament, so as to be entirely protected. He had used this method in a large number of cases, and with entirely satisfactory results.

Abdominal Section for Tuberculous Disease.

DR. THOMAS E. MCARDLE, of Washington, D. C., reviewed briefly what has already been done by surgical means for the relief of women suffering from tuberculosis of the generative organs. There is no doubt that tuberculous disease of the female genitalia is more frequent than is generally supposed. Every portion of the genital tract may be affected, the order of frequency for the various portions being the tubes, body of the uterus, ovaries, vagina, cervix, and vulva. The tubes are affected in nearly all cases, the body of the uterus in about three-fourths of the cases, and the ovaries in about one-half of all cases. Tuberculosis of the body of the uterus is not at all a rare affection and has been frequently discovered in autopsies upon phthisical subjects. It can be the only focus of disease in the body, but it is generally associated with disease of the tubes and is secondary to disease of that organ. Of all the female genitalia, the vulva is the least liable to tuberculous infection.

Melano-Sarcoma of the Female Urethra.—DR. CHARLES A. L. REED, of Cincinnati, O., reported this case: Mary E. Y—, aged sixty-four, single, was brought to his private hospital December 3, 1895. The patient had had no previous serious illness. There was no history of tuberculosis or syphilis in the family. The virginal condition of the genitalia precluded the supposition of venereal infection of any character. Her general health was good, although there was some emaciation about the neck and breasts, the latter of which were flabby—changes no doubt incident to age. Careful examination revealed no diseased conditions about either the lungs or heart. Careful palpation and percussion of the abdomen yielded negative results. About eight months previously,—*i.e.*, in April, 1895—she began to notice some pain accompanied with blood on micturition. This was shortly followed by a more or less constant pinkish discharge from the genital fissure. The self-examination which followed revealed a tumor at the meatus urethræ. This tumor continued to increase in

both size and hemorrhagic tendency until she was prompted to consult Dr. Morris, who curetted the neoplasm thoroughly and treated it with styptics. When the patient came under Dr. Reed's care he found a black lobulated and eroded mass about three centimetres in diameter separating the labia majora. The orifice of the urethra was in the very centre of this mass. A careful vaginal examination was not made at the time, as the virginal structures, present in their integrity, rendered such an operation very painful. Operation was done the next day, December 4th. The small blade of a Jones speculum was introduced; the patient being in the Simon's posture, the urethra was by this means exposed in its entire length. A longitudinal incision was made through the mucous membrane along the dorsum of the urethra from a point where the presenting part of the mass was eroded to the base of the bladder. Another incision through the mucous membrane was made at right angles to the foregoing at a point far enough above the eroded mass to insure healthy tissue. The mucous membrane was then dissected back in two lateral flaps and the urethra was enucleated. The urethra was found to be distinctly conical in shape, the base of the cone being at the meatus, the apex at the bladder. Care was taken to dissect out the canal to a point manifestly above the zone of malignant involvement. When this point was reached but a slight distance from the bladder, the canal, with the neoplastic walls, was excised. The cut margin of the cystic segment of the canal was seized at various points in its circumference by Kocher's forceps, brought down by gentle traction, and fixed by interrupted sutures of silkworm gut to the vaginal mucous membrane. A self-retaining catheter was inserted, and the patient was put to bed. The sutures were removed on the eighth day. The catheter was dispensed with on the twelfth day. The patient sat up on the fourteenth day, when she found that she could retain her urine and void it at will. She was dismissed December 21st, entirely healed. She remained in good health until the 1st of July following—seven months—when she again summoned Dr. Morris because of some stomach symptoms. He found her suffering from persistent vomiting, and with a large mass in the epigastrium. This mass rapidly increased in size until it occupied all of the area between the navel and the breast bone, its nodular characteristics becoming more and more pronounced. She died of exhaustion July 14, 1896, having had no recurrence whatever of the urethral trouble. No autopsy was permitted.

Suture of Large Vessels Injured in Operations.

—DR. J. B. MURPHY, of Chicago, demonstrated the method employed by him. He said in 1762 Lembert conceived the idea of suturing injuries to vessels. He made two experiments, in both of which he failed. Dr. Murphy then referred briefly to the experimental work of other surgeons along this line, pointing out their successes and failures. His own researches and operative work lead him to believe that, when a large vessel is injured in an operation necessitating a transverse division of it, not exceeding two-thirds of its circumference, the surgeon can resort to immediate suture without resection, and, if the field of operation be aseptic, can feel more certain that he will have union of the vessel and continuation of the current than he could when he sutures the intestine as for resection of the bowel. He believes from his observations that the chances are better with the suture. The importance of this concerns surgeons more in the treatment of aneurisms. Coming to the question of stab and bullet wounds of the extremities, he said there was a great field for improvement in past operative work. Formerly, we ligated vessels, and when this was done the inevitable result was death of the limb. He be-

lieves that now such limbs can be uniformly saved, particularly in the aseptic cases. With his present method of suturing large vessels, he is not afraid to suture any vessel in the body, feeling confident that adhesion or union will take place.

Contusions of the Abdomen.—DR. W. G. MACDONALD, of Albany, N. Y., presented a communication with this title. Contusions of the abdomen, he said, are always grave injuries. The question of surgical intervention, although much discussed, cannot be regarded as satisfactorily settled. Seven cases of traumatic rupture of the stomach and small intestine were reported. Two operations were undertaken, with one recovery and one death the eighth day after operation from second rupture. All the inoperative cases resulted fatally. Reference was made to the general absence of evidence of contusions in the abdominal walls when serious visceral injury has occurred. Very slight causes, particularly if the intestinal canal is distended with fluids, may produce intestinal rupture, as the falling out of bed, a blow from a barrow handle. The early symptoms of intestinal laceration are not always distinctive. An analysis of two hundred cases of intestinal laceration as associated with abdominal contusion was made with a view to determining the symptoms. The following topics are considered the important ones: History of the nature of the injury, shock or collapse, pain, vomiting, pulse, temperature, and physical signs. Careful investigation of a given case will usually show sufficient symptoms to make an early exploratory abdominal section imperative.

Election of Officers.—The following officers were elected: *President*, Dr. James F. W. Ross, Toronto, Can.; *First Vice-President*, Dr. George Ben Johnston, Richmond, Va.; *Second Vice-President*, Dr. John C. Sexton, Rushville, Ind.; *Secretary*, Dr. William Warren Potter, Buffalo, N. Y.; *Treasurer*, Dr. N. O. Werder, Pittsburg, Pa.

The next meeting will be held at Niagara Falls, on August 24, 25, and 26, 1897.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-Second Annual Meeting, Held at St. Paul, Minn., September 15, 16, 17, and 18, 1896.

THE association convened in the senate chamber at the Capitol. DR. C. A. WHEATON, chairman of the committee of arrangements, called the meeting to order. MOST REV. JOHN IRELAND, D.D., offered prayer. On behalf of the State of Minnesota, Gov. D. M. CLOUGH gave an address of welcome. The physicians were welcomed on behalf of the city by MAYOR F. B. DORAN. He referred to the city's reputation as a host, won by the magnificent record of the recent Grand Army encampment, and that upon that occasion St. Paul had welcomed the men who had preserved the nation, and now was happy to welcome the men who preserved the bodies of the nation's defenders. DR. A. J. STONE spoke for the profession in St. Paul, in extending a welcome to the visitors.

President's Address.—DR. HENRY O. WALKER, of Detroit, delivered the address. He said he had found it difficult to secure a subject which had not been thoroughly threshed over and over again. He had, therefore, departed from the usual course, and would offer some suggestions in a purely scientific vein, by reporting three cases, in which four operations were done, representing nearly all the operative procedures now done upon the kidney.

Sacculated Kidney and Nephrolithiasis.—August 4, 1896, J. R.—, aged twenty-nine, was referred to him for operation, with a history of severe pain in the

left kidney twenty years previously. The attacks recurred at intervals of from one to three months. This condition continued with increasing severity until three months before the speaker saw him, when the pain became constant. There was sediment in the urine for nearly fifteen years. Examination of the urine showed pus in quantity, blood at times, but no casts. The patient presented marked emaciation, rapid pulse; temperature, 99.6° F.; percussion revealed well-marked dullness on the left side. Nephrolithotomy was first performed, and subsequently nephrectomy.

Tuberculous Kidney.—The diagnosis was disease of the right kidney. Microscopical examination failed to reveal bacilli, but showed large quantities of pus and epithelium. A nephrectomy was done, August 16, 1896. The nuclein treatment was instituted, with marked improvement, until the patient left the hospital, September 9th.

Movable Kidney.—In this case the signs were chronic constipation, flatulence, indigestion, supra-orbital neuralgia, and pain in the right hypochondriac and lumbar regions; there was a freely movable tumor in the right hypochondriac region. A diagnosis of movable kidney was made. The kidney was placed in its proper position, and the capsule was divided for a distance of three inches on its convexity. The capsule was then separated from the kidney for one inch entirely around the cut. The cut edges were fastened to the fascia and muscle by interrupted catgut sutures, so that when the suturing was complete there was a solidity of fixation of the kidney. The most practical route to the kidney, the speaker said, is the anterior one. The selection of the lumbar route is largely a following of precedents. A nephrectomy for tuberculous kidney is not always practicable. Fixation of a movable kidney is best done by stitching its reflected capsule to the muscles.

A New Operation for Cleft Palate.—DR. TRUMAN W. BROPHY, of Chicago, read a paper with this title. He took the ground that the operation should be performed much earlier than has been the custom of surgeons heretofore. It has usually not been thought advisable to operate for the closure of cleft palate until the child has reached the age of from two to five years. He held that when the operation was thus postponed the changes in the voice had become permanent, and a repair of the cleft at that time would not influence favorably voice production. His operation consisted in freshening the edges of the cleft; then, by deep suture of silver wire fixed through a lead plate, conforming to the palate, the edges of the cleft were drawn together and so maintained until healing took place.

DR. W. F. DALY, of Pittsburg, complimented the author in presenting a method so markedly original, and one which did away with all the objections to the old operations.

The Psycho-Neural Factor in Clinical Medicine.—DR. C. H. HUGHES, of St. Louis, Mo., read the paper. He said that the physician must consider the whole mechanism of the system when treating any one part. Some parts of the body influence the whole less or more than others. The surgeon must consider the susceptibility, predisposition, powers of resistance, recuperative powers, and natural courage of the patient, in determining as to the prognosis or operation. In any case the nervous system is either for or against him. Painful ovaries are not necessarily to be cut out, but to be cured by neurological treatment. The surgeon must have a wide neurological and psychiatric knowledge if he would avoid fatal mistakes. Much can often be done in improving the case by tranquilizing neurological treatment. In fatal surgical cases the results are often due to overlooked neurological conditions.

Trunk Anæsthesia in Locomotor Ataxia.—DR.

HUGH T. PATRICK, of Chicago, read a paper on this subject. He said in nearly all cases of tabes dorsalis there is a band of anæsthesia about the trunk at the level of the nipple. It is, early in the disease, very narrow or even incomplete, or may be represented by a zone in which the localization of touch is not normally accurate. The sensory blunting on the leg, so frequent in tabes, is generally an analgesia. The trunk anæsthesia is essentially tactile, and the pain sense may be quite normal. The band of anæsthesia does not correspond to the cutaneous distribution of the intercostal nerves, but to the nerve fibres arising from adjoining segments of the spinal cord. In some cases there are two distinct zones of anæsthesia, indicating simultaneous involvement of spinal segments at some distance from each other. The borders are inconstant, ordinarily retract on continued testing, and vary in position with the method of examination. The same band of anæsthesia may occur in syphilitic pseudo-tabes, as shown by an illustrative case, as far as known the only one on record. The patient presented nearly all the symptoms of locomotor ataxia, including a wide band of trunk anæsthesia; but a diagnosis of syphilitic disease of the cord was made, and under an active specific treatment he made an almost perfect recovery.

DR. HUGHES, of St. Louis, said that it was not surprising that these peculiar areas of anæsthesia should be found in locomotor ataxia, considering that the entire symptom complex of the disease is due to disturbance of the sensory mechanism.

Treatment of Some Inflammatory Diseases of the Gastro-Intestinal Tract.—DR. GUSTAVUS BLECH, of Detroit, read this paper. He said that the treatment of catarrh and other inflammatory conditions of the stomach, as it is practised to-day by most medical men, meets with failure because the treatment is directed against the symptoms and not against the cause of the disease. All the usual remedies may improve one or the other symptoms for a limited time, but, the etiological morbid conditions still remaining, the symptoms necessarily will appear again. The treatment should be directed against the inflammation itself. He was accustomed to prescribe hydrozone, well diluted in water, at least a quarter of an hour before each meal.

DR. DALY, of Pittsburg, deprecated the very general use of hydrozone and such remedies, unless a very careful and discriminating diagnosis had been made.

DR. PATRICK, of Chicago, was sorry that he could not agree with the author; but he could not until it was explained which variety of inflammatory condition in the stomach was referred to. Gastritis is too comprehensive a term. When a cure is proposed, we must know what form of gastritis we have to deal with.

DR. I. A. ABR, of Chicago, said that all the diseases of the stomach cannot be grouped together as gastritis. Many of these conditions are due to toxins found in the gastro-intestinal tract. We cannot always make a positive diagnosis at once, but by experiment only can we arrive at definite conclusions. Any one remedy cannot and will not answer for all cases.

DR. LARRABEE, of Louisville, said that he was convinced that the portal circulation is a most important factor in these cases, and one, too, which is often overlooked. Exercise is of paramount importance in all cases of chronic gastritis.

The Therapeutic Action of the Antitoxins.—DR. E. M. HOUGHTON, of Detroit, read a paper with this title. The author reviewed the theories of orrhoterapy, demonstrating the differences between toxins and antitoxins. It has not as yet been shown, he said, just how the antitoxin counteracts or destroys the toxin. He injected three guinea-pigs with toxin cultures, the other three with toxin and antitoxin cultures mixed.

The discussion of the paper was postponed until the result of the injection on the animals should be determined.

Reinfection in Consumption.—DR. JOSEPH MUIR, of New York, read the paper. Statistics show that a first attack is not usually fatal, and death is often found to be due to other causes. Primary infection is not usually due to inherited tendencies, but external conditions play a most important part. Consumption is best treated among the rich—frequently, indeed, a permanent cure is effected in this class of cases; so for evident reasons those who are poor should receive especial attention. Patients who have been cured must not be allowed to return to their former environment. Change of air and outdoor exercise and labor harden and refresh the tissues, and the respiratory impurities of former environment are no longer present. Reinfection may be prevented by thorough disinfection of the patient and surroundings, and destruction of the sputum. This protects the patient against himself.

Removal of the Gasserian Ganglion.—DR. J. B. MURPHY, of Chicago, read a paper on the indications for this operation. He demonstrated the technique of the operation on a cadaver. The operation might seem heroic, but heroic measures were necessary in a condition so severe as trigeminal or facial neuralgia. These patients would submit to anything in the hope of relief. This method of operating was more simple, as well as more certain in its results, and resulted in less deformity, than any other yet suggested. The speaker always suggested some medicinal treatment, especially by castor oil, before resorting to so heroic and serious a measure as this operation. The trouble, however, with all measures was that they do not give a permanent relief. The castor-oil treatment has given temporary relief in several cases.

DR. A. J. OCHSNER, of Chicago, had recently had some experience in these cases in the use of castor oil. He had given the remedy in half-ounce doses twice daily for ten days or two weeks at a time, and to his surprise it had proven to be an excellent remedy. As to whether the results will be permanent, he could not say, but no case had yet returned to its former severity. He would repeat the castor oil whenever there were indications of a returning attack.

Electro-Diagnosis and Electro-Therapeutics Simplified.—DR. HUGH T. PATRICK, of Chicago, read a paper with this title.

Electro-diagnosis is limited to the affirmation or denial of a lesion of the lower neuron; that is, of a lesion of the motor cells in the spinal cord, or of the nerve fibre, the peripheral nerves springing from those cells. A lesion of this neuron causes the reaction of degeneration, and this, stripped of all unnecessary technicalities, may be recognized by two variations from the normal, namely, a loss or very considerable diminution of faradic contractions, and the slow wormlike contraction of the muscles in response to interruption of the galvanic current. In the electro-therapeutics of organic disease of the nervous system, applications of electricity through the brain may be entirely discarded as useless. Electricity through the spinal cord is little better. In diseases of the peripheral nerves it probably hastens recovery, and that current is to be chosen which the better causes muscular contraction. In functional nervous disease electricity is of more practical value than in organic affections, but it is almost impossible to determine what proportion of this good effect is due to mental impression—to suggestion. The galvanic current is chosen for facial and costal neuralgia, and sciatica; the faradic for lumbago, hysterical anæsthesia, paralysis, and pain; the galvanic for exophthalmic goitre and sometimes for neurasthenic headache and backache. For facial spasms, tic, spasmodic torticollis, tremor,

and chorea; electricity is useful aside from the mental effect. The highly practical and otherwise unusual merits of the paper were touched upon in the discussion which followed; all agreeing in the verdict that the subject of electricity had been presented in a most practical as well as scholarly form by Dr. Patrick.

A New Method of Fastening the Round Ligament in Alexander's Operation.—DR. J. FRANK, of Chicago, read this paper. An incision an inch long is made midway between the anterior superior spine of the ilium and the spine of the pubes, a trifle above Poupart's ligament. The transversalis muscle is pushed back and the ligament is drawn out with a blunt hook, until the uterus is in the correct position. Usually three sutures are required to close the wound, the first one being taken as low as possible through one flap of the peritoneum, then through the round ligament itself. Instead of drawing the ligament through the fascia, as formerly practised, it is replaced in its anatomical position beneath the transversalis muscle. By this method a slough of the ligament is prevented. This operation is the simplest of all yet proposed for the purpose. A pessary should be fitted in before the operation, and worn as long as may be necessary afterward.

Tonsillotomy by Cautery Dissection.—DR. J. HOMER COULTER, of Chicago, read a paper on this subject. No subject in surgery or medicine has been much more prolific in interest and discussion than that of the tonsil. In the past ten years over six hundred papers have been written on that subject alone. The size of the normal tonsil is still a subject of discussion with throat specialists. Some claim there is normally no tonsil to be seen; however, the most usual opinion is that there exists normally a collection of follicles between the pillars of the fauces, protruding slightly above them. The tonsil is an almond-shaped gland larger at one end than the other and somewhat flattened.

The methods usually employed for its ablation are the guillotine, ignipuncture, the cold or cautery snare, or the knife. Each of these methods has practical objections to its use. Most important of these objections and one which applies to all of them is the fact that by no one of them can the entire gland be taken out. Unless this is done the part remaining will oftentimes produce as much trouble as did the former condition. The operation he proposed obviates this objection entirely if properly performed.

With a well-heated small electrode the pillars are dissected away from the tonsil to one-half its extent. The gland is then, with suitable forceps, drawn well out and thoroughly and entirely dissected out to about one-half its extent. This portion is then cut off and the surface treated with a strong solution of silver nitrate. In a week or ten days the other portion of the tonsil is removed in the same manner. This operation will give cosmetic as well as practical results unobtainable by any other process yet suggested.

The Surgical Treatment of Pyloric Obstructions was the title of a paper read by DR. W. J. MAYO, of Rochester, Minn. He said that this subject had not received the attention it demands from American surgeons. The differential diagnosis of serious pyloric disease was often a matter of the greatest difficulty. He had found the free exhibition of strychnine for several days previous to the operation of great value in preventing shock. The stomach should always be thoroughly washed out a few hours before the operation and nothing eaten afterward. For combating the shock, besides strychnine and dry heat, a rectal enema of a pint of hot coffee should be given. Nourishment by the stomach should not be too long withheld afterward. For twenty-four hours rectal alimen-

tation should be used; in thirty-six hours some champagne, later buttermilk, and then a gradually increasing diet may be given by the mouth.

Submucous Linear Cauterization; A New Method for Reduction of Hypertrophies of the Conchæ.—DR. NORVAL H. PIERCE, of Chicago, read a paper on this subject. He called attention to the various methods ordinarily used for the reduction of such hypertrophies, and showed the disadvantages of each. The differentiation between hypertrophy and turgescence was pointed out. The operation proposed by the author was as follows: A small incision is made in the hypertrophied membrane, then with a blunt flat probe the mucous membrane is carefully separated from the erectile tissue underneath. Then a sound, the end of which is cup-shaped and upon which have been fused a few crystals of chromic acid, is inserted in the incision and the track already made by the probe is thus cauterized. The advantages of this method are that there is no hemorrhage; it is less painful than by any other method, the functional activity of the mucous membrane is not in the least impaired. Patients will submit to this operation more willingly than to the burning of the cautery. The method is the most simple of any yet suggested. The reaction is usually insignificant. There is no slough. The danger of atresia is obviated.

The Relationship of Diagnosis to Future Surgical Progress.—DR. HORACE H. GRANT, of Louisville, delivered the address on surgery, taking this for his title. Some common ground must be chosen on which we can equalize our differences. Many of the most recent operations are already passing away under the effect of our modern scrutinizing investigation. We forget there are men in the quiet of their laboratories doing a work which makes all our wonderful progress possible and gives us these new methods. We cannot progress much farther in technique or operative skill. Any great amount of paraphernalia suggests a lack of personal resource in the operator. Almost every part and organ of the human body has been removed, recently, with more or less good to the patient. If we would make earlier and more careful diagnoses, many of the possible failures would be precluded. No surgeon dare say to the patient: "If I had known yesterday or before, thus and so, the result would have been different." Are we not at fault sometimes ourselves? Rarely will we fail to secure an operation if the operator be certain of his diagnosis and demand the operation.

No term in all surgery is so often misapplied as conservatism. No aim is dearer to the surgeon than the ways and means of relieving his patient. We must not fall into the error of making one man great and another insignificant. The experience which age gives some men leads them to make valuable and correct diagnoses. Experience is and should be one of the greatest aids in diagnosis. The skiagraph has lately come into importance in surgical work, and it may be made an excellent adjunct in many instances. Its recent successes are noteworthy. It is yet, however, in its infancy, and doubtless is capable of still more development. May we not soon expect to see the fetus *in utero*? No one doorway can open to the royal road to success in the practice of surgery. The skilful and intelligent application of prompt relief, added to a careful diagnosis, will give us the most wonderful and satisfactory results. What each one finds to do, let him do it with his might.

Appendicitis; to Operate or Not to Operate.—DR. JAMES H. DUNN, of Minneapolis, read a paper with this title (see p. 508).

DR. J. B. MURPHY, of Chicago, said that the surgeon is brought face to face with a condition which has a recognized mortality of from about five per cent.

to eight per cent. He thought such a percentage is too high. We first have to contend with the presence or absence of a suppuration. In four hundred and fifty cases he did not think there had been an entire absence of pus in one single instance. He was satisfied there are some cases which can be cured by medicine, but can they be differentiated? By medical treatment we have a mortality of ten per cent., and if we have three per cent. by the knife then we must operate to save the other seven per cent. Not every case can be operated upon, but the conditions will show whether or not it is advisable.

Nerve Sutures and Other Operations for Injuries to the Nerves of the Upper Extremity.—

DR. A. J. OCHSNER, of Chicago, read a paper of which the following were the conclusions: 1. Every severed nerve should be sutured even after years. 2. The earlier the operation is performed the better. 3. If neither sensation nor motion is established within a year, the nerve should again be exposed, the cicatricial tissue removed, and the end again sutured. 4. The end should be clean cut, should contain neither crushed tissue nor cicatricial tissue. 5. Tension must be avoided. 6. The wound must heal without suppuration to secure the best results. 7. Hemorrhage should be perfectly controlled to prevent intervening clot. 8. Carefully prepared catgut is the best suture material. 9. After suturing the ends, either direct or "*à distance*," it is well to stitch a fold of fascia over the united nerve ends. 10. The extremity should be placed at rest. 11. The external incision should be ample.

Woman and Her Diseases versus Gynecology.

—DR. HENRY P. NEWMAN, of Chicago, read a paper with this title. We are coming, he said, to a period of transition in the practice of surgical gynecology; instead of essays on the treatment, we now have studies on the cure and prevention. Preventive medicine, hygiene, sanitation, and sociology are now popular themes for medical societies. Philanthropy has taken the cue from medicine, and is attempting to form a citizen rather than reform him. He desired to emphasize the fact that we are not dealing with the cold-science side of our art, but with the highest of humane interests. The amount of ignorance in the average woman of nature's requirements is appalling. Woman's sphere has lately widened until now it is as wide as man's, but she has not equipped herself for this race. Women in the cities—the stenographers, saleswomen, business women—daily outrage their bodies by compliance with the dictates of fashion in food, dress, and habits. The tendency of gynecologists to practise surgery is to be deprecated. It narrows his opportunities. He had better stay attached to obstetrics and pædiatrics. A woman's generative organs should not be doomed because she has had to visit the gynecologist. A good diagnostician must know as much about woman as about disease; as much about environment and social and domestic relations as about pelvic lesions. As specialists we must recognize and exercise the important interests in a medical science which will prevent rather than cure disease. As we know, what can be acquired may be prevented, hence we as specialists should lead in the reform of those conditions which are detrimental to the health of woman.

The Pathology and Treatment of Suppurative Salpingitis was the title of a paper read by DR. F. F. LAWRENCE. The tubal mucosa is a true mucous membrane, possessed of all the histological elements of mucous membrane. The fimbriæ are prolongations of the folds of mucous membrane, with a few muscular fibres beyond the end of the tube. The closure of the end of the tube is effected by, first, the unfolding of these plicæ and the elongation of the muscular fibres with coincident inflammatory exudate, and not by

adhesions of the peritoneal surface; second, the formation of adhesions between the fimbriæ and other structures; third, embedding of the fimbriæ in inflammatory exudate. The closure of tubal ostia results in the forming of circumscribed abscess, the pathology of which is the same as that of suppuration with abscess formations in mucous membrane in other parts of the body, except for its effect upon important contiguous tissues. Occasionally the uterine end of the tube remains patent, when we have the abscess in the tube communicating with the uterine cavity, through which it may in part discharge its contents. The treatment of pus tubes cannot be fixed by any ironclad rule. Each case must be treated according to the conditions there presented. We must even incise and drain in some cases. Seldom will vaginal section be required, and then only in carefully selected cases. Hysterectomy is indicated in those cases in which we find abscess of the uterine wall, tuberculous deposits, fibroids, or malignant disease in the fundus. As hysterectomy destroys the pelvic floor, it should never be performed except when there is some tangible lesion of the uterus. Abdominal section will be necessary in many cases.

Importance of Physical Signs Other than Murmur in the Diagnosis of Valvular Disease of the Heart

was the title of a paper contributed by DR. JAMES B. HERRICK, of Chicago. Standard text-books teach that an endocardial murmur is not always an evidence of a valvular lesion, and also that a valvular defect may exist and still no murmur be present. Practically, however, conclusions are usually based upon the presence or absence of murmur. This is wrong, for there may be a valvular disease without a distinct murmur being audible. Other findings than murmur must be used in determining the existence of a valvular lesion. Every valvular lesion must result in hypertrophy and dilatation of the heart behind the valve diseased. An increase in tension of the pulmonary circulation follows any valvular lesion at the mitral orifice, and later any aortic disease. This will show in increased force of the pulmonic second tone. Stenosis of the orifices of the left heart means a smaller amount of blood in the general arterial circulation: therefore, lessened arterial tension. Failure of the right heart is followed by venous congestion, *e.g.*, venous pulse, hepatic and portal congestion, anasarca, etc. Hypertrophy may be recognized by the heaving, forcible apex impulse. Epigastric pulsation may call attention to enlarged right heart. The jugular pulse, the hepatic and capillary pulse, are all of diagnostic value. The visible pulse of aortic regurgitation is almost pathognomonic. Palpation is important. Extra-cardiac causes for murmur, such as might arise in a heart dislocated by pressure or retraction, can usually be excluded by percussion. A weak aortic sound may be an indication of obstruction. The reduplicated second sound may point to valvular disease. A sharply accentuated first sound at the apex is common in mitral stenosis. The peripheral tones in aortic regurgitation are a valuable confirmation. Error in calling an inorganic murmur organic is readily made, unless the secondary sounds are carefully sought for. The intention of the paper was not to undervalue the importance of endocardial murmur, but to insist that it is only by the complexus of signs and symptoms that an accurate diagnosis can be made. Of all the evidences of heart disease, the least valuable is the endocardial murmur.

Value of Secondary Physical Signs in the Diagnosis of Cardiac Diseases.—DR. R. H. BABCOCK, of Chicago, reported a case illustrating this. Among other points brought out were: Murmurs are the least reliable signs of valvular disease. An accurate diagnosis cannot be made unless the secondary signs of

valvular disease are recognized. If the heart actions are not sufficiently strong there may not be any murmur; or a grave defect may not be observed for the same reasons. Secondary symptoms are a modified pulse rate, character, and rhythm, leading to a congestion of the veins and internal organs. In some instances there is also systolic venous pulsation of the liver. Such systolic jugular pulsation is diagnostic of insufficiency, even if the murmur is not audible.

Water.—DR. I. N. LOVE, of St. Louis, read a paper with this title. Drugs, he said, seemed to be the chief inspiration in the life work of too many men. Hydrotherapy has been a wonderful service to humanity. We can appreciate the necessity of water when we remember that seventy-five per cent. of our body is made up of water. It is just as important as the solids in life's conditions. The demands for water are affected by the amount of muscular exercise and degree of temperature to which the body is exposed. For an irritated stomach or bilious colic, nothing is superior to liberal quantities of hot water. We need water for nutrition, but also for a proper elimination. Water taken freely acts as a purifier of the system, both by flushing and by its solvent action. The majority of people drink too little water. The speaker advised that children be trained to drink more water. It is a most important agent in improving the complexion. Medicine should be given in large quantities of water. In typhoid fever he insisted upon free drinking of pure water. No solvent will act better in removing uric acid from the system, and the only pure water is distilled water. Copious draughts of water, for its stimulating effect or the reduction of temperature, have been used for many years. The hot pack in convulsions of children is often misused. Better begin with a tepid heat and add cold water gradually. Hot water locally in inflammatory conditions is most excellent.

DR. MANLEY, of New York, said that he had often thought that if we only realized what could be accomplished with water in a medicinal way, its use would be more general. He was strongly impressed with the fact that many of the bowel and bladder conditions could be most effectively treated by the proper use of water. In the case of cystitis, he knew of nothing that would take the place of water. Often he had thought the surgeon's knife might be laid aside if we knew how to use water. A large number of the cases of appendicitis, in his opinion, might be relieved by a thorough washing out of the bowel.

DR. HUGHES, of St. Louis, said that the value of water had not been overdrawn by the author or in the discussion. He was opposed to limiting the amount of water used at and during the meal time. Its action is not only eliminative, but stimulating to both kidneys and bowels.

DR. STUCKEY, of Louisville, would take issue with the author on the idea that large quantities of water should be taken along with the food. He could not see how it would increase or aid in the digestive function in the stomach, but its importance after digestion is ended could not be overrated.

DR. BABCOCK, of Chicago, said that in some cases of Bright's disease it had seemed to him that a sufficient quantity of water might have prevented the condition. If the bowels be constipated and the skin dry, increased work is thrown upon the kidney. Professional men, men of sedentary habits, and women will often escape the severity of Bright's disease by the unlimited use of water.

DR. HENDERSON, of St. Paul, wished to ask the author whether or not the taking of large quantities of water would increase the fat formation. Does the fat man take water because he is fat, or is he fat because

he takes water? The speaker was a lean man, and did not drink water except in the morning.

DR. TURCK, of Chicago, said that the first indication was to find out what the pathological conditions are which are to be met by the water therapy. We must know the condition of the stomach before advising the ingestion of large quantities of water. The habit of taking great quantities of water into the stomach, even two hours after a meal, will hinder the process of digestion. On the other hand, if there is an accumulation of material on the walls and other viscera, then the taking of water would not be objectionable.

DR. LOVE, in closing, said that it is what is taken into the stomach as food and becomes nutrient that leads to development, continued health, repair, and elimination. In these processes water has an important part, if taken in the right way. He did not advise that large quantities of water should be taken while eating, but moderate quantities could not possibly interfere with the digestive processes.

The Clinical Significance of the Child's Fontanelle.—DR. ISAAC A. ABE, of Chicago, read a paper with this title. In health the fontanelle does not sink below or rise above its bony frame. It has both respiratory and pulsatory movements. With increased intracranial pressure the normal bruit may quite disappear. An early ossification interferes with brain development and produces a brachycephalic skull. In rachitis the involution of the fontanelle is delayed. Marked bulging is caused by the collection of fluid within. The abnormal retraction of the fontanelle always indicates a condition of inanition. It may be temporary; if chronic, it is a serious condition. A deeply-sunken fontanelle is always a danger signal in any case. Involution occurs normally at fifteen to eighteen months. Protuberance and tension indicate meningitis.

Operative Treatment of Pterygium was the title of a paper read by DR. EDUARD BOECKMANN, of St. Paul. The author discussed the history of the operations for the cure of pterygium, pointing out the objections as well as the advantages of those most frequently used. He suggested an operation which was a combination of some others referred to. A crescentic piece is cut from the pterygium about five lines from its head. This part is curetted thoroughly down to the sclerotic. The head of the pterygium is dissected off. At the convexity of the piece cut out a stitch is inserted and the opposing edges are drawn together. This leaves the curetted portion to granulate, and form a cicatrix. The author thinks the result from this method superior to that of any other in his experience. The paper was discussed by DRs. WILDER and BUCKNER.

Subconjunctival Injection in the Treatment of Certain Diseases of the Eye.—DR. WILLIAM H. WILDER, of Chicago, read the paper. The method consisted in the injection beneath the conjunctiva of minute quantities of bichloride of mercury or cyanide of mercury in solution. The operation was not especially painful unless there were inflammation present. It had been advocated for many other conditions and diseases. Its exact limitations and indications were not yet positively decided upon. It had been impossible to get the same good results from the salt injections that could be obtained from the mercury. We had in this new treatment a powerful adjunct to the old and tried methods in some diseases of the eye, but it was not to be employed to the exclusion of all others. It was not a panacea, but in cases in which the mercurial treatment was indicated it was an excellent method.

DR. BUCKNER, of Cincinnati, could see the special advantage in injecting the solution of mercury under

the conjunctiva over the old method of administering the drug hypodermically or through the mouth.

DR. BOECKMANN said that he had used these injections since he first commenced to practise medicine, but he was still unable to say just how much good they really do. He carefully injected these solutions whenever he found an ulceration of the cornea. In some cases he had found it to act beautifully, in others it was a failure.

The Use of Oxygen in Chloroform Narcosis.—DR. C. B. PARKER, of Cleveland, O., read a paper with this title. The exhibition of the vital principle, oxygen, with chloroform would seem to be proper on theoretical grounds. In uniting the two there is no chemical union formed between them. It is a mechanical mixture, such as we have in the air. The oxygen must be perfectly pure. That usually supplied in tanks is not pure. It must be properly made. The cylinder must have been exhausted of all air before it is filled. The time required to anesthetize is slightly longer than with chloroform, but the advantages far outweigh this minor inconvenience. Of the dangers attendant he was not prepared to say: as he did not consider an experience of one hundred and eighteen cases guarantees any statement relative to that point. There is total absence of vomiting, as well as absence of the extreme pallor and weakened heart beats with shallow respiration. The duration of the shock from anesthesia is with this agent very much shorter. The patient always recovers promptly without any delirium.

The Election of Officers resulted in the choice of the following: *President*, Dr. Thomas Hunt Stuckey, Louisville; *First Vice-President*, Dr. Charles A. Wheaton, St. Paul; *Second Vice-President*, Dr. Paul Paquin, St. Louis; *Secretary*, Dr. H. W. Loeb, St. Louis; *Treasurer*, Dr. W. N. Wishard, Indianapolis; *Member of Judicial Council*, Dr. H. T. Patrick, Chicago.

The next meeting will be held at Louisville, on the third Tuesday of September, 1897.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 28, 1896.

E. D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

Nominations.—The following were nominated for office: For *President*, Drs. A. M. Jacobus, Landon Carter Gray, E. D. Fisher (declined), H. D. Chapin, Frederic Petersen, H. J. Garrigues, Richard Van Santvoort; *First Vice-President*, Dr. R. A. Murray; *Second Vice-President*, Dr. N. E. Brill; *Secretary*, Dr. C. H. Avery; *Assistant Secretary*, Dr. W. E. Bullard; *Treasurer*, Dr. John S. Warren; *Censors*, Drs. S. D. Powell, H. L. Collyer, Frank Van Fleet, S. Marx, E. D. Fisher, B. F. Curtis, F. M. Crandall, W. L. Carr, H. N. Vineberg.

Remarks upon the Causes and Prevention of Chronic Catarrh of the Nose, Throat, and Ear in Young Children.—DR. WENDELL C. PHILLIPS read the first paper of the evening. Chronic catarrh of the nose, throat, and ear in children was frequently referred to some one of the exanthemata as the starting-point, and correctly so in many instances. Measles and scarlet fever were most often to blame. It must be borne in mind, however, that the exanthemata occurred at a time of life when catarrhal diseases were apt to arise from other causes. Syphilitic and tuberculous cases constituted a class by themselves. An internal deformity or malformation of the nasal tract might be inherited. Climate was an important factor, but the author thought Bosworth was correct in the

view that it could only aid other factors. An acute rhinitis, or cold in the head, was regarded by most writers as one of the chief causes of chronic catarrh in various forms. Among other causes named were improper or insufficient ventilation of sleeping and living apartments, the presence of large masses of lymphoid tissue, injuries to the nose resulting in deformity of the septum or displacement of the turbinates. When the cause was mechanical, the development of the catarrhal process was often slow, but might be rapid. Speaking of prevention, he said physicians were often careless in the management of the exanthemata, in not giving due attention to the upper air passages. During convalescence, when nature was trying to reassert herself, aid should be given by use of antiseptic and soothing applications. One author had found that out of six hundred cases of the class under discussion, 12.5 per cent. had originated during scarlet fever; twenty-six per cent. during measles. The nose should be frequently and thoroughly cleansed in these affections, a spray or douche of warm antiseptic saline solution, like Dobell's, or solution of boracic acid, etc., or oily spray being used. Whatever medication was used, it should be bland and non-irritating. Steam was very soothing, and was highly recommended. To the fluid one might add oil of menthol, etc.

Change of climate afforded temporary relief in many cases, and a permanent change of residence might become necessary when other measures failed. Lymphoid tissue, whether present in large or small quantity, should be removed. Due attention to adenoids would diminish the number of institutions for the deaf. Colds existed most frequently among children who were coddled and kept indoors, in heated and badly ventilated rooms. They ought to live more out of doors, not only in pleasant but even in threatening weather, and should be sponged daily with cold water. Many parents had come to recognize that children raised in this manner had even better health than those raised in the country, under usual conditions prevailing there. There might be practitioners who told parents to let these chronic affections alone and they would after a time disappear, but the writer had found such advice was the exception. At first many children objected to the nasal spray, but under gentle management they ceased to oppose it. When there was mucus in the nose, especially when it became inspissated, there should be daily cleansing. Every physician should be able to make an intelligent examination of the nose, and in a case of injury correct the displacement at once. Operations should never be undertaken upon the nose of children except when there was such deformity or destruction as would lead to tissue changes. In conclusion, the author reminded the family physician of the grave responsibility resting upon him in preventing chronic affections of the nose, throat, and ear.

Familiar Ground.—DR. JAMES E. NEWCOMB, in opening the discussion, said the paper had covered familiar ground, and there should not be great difference of opinion. The exanthemata certainly constituted a frequent cause, and sometimes, in spite of much care, we found our efforts at prevention of no avail. Enlargement of the glands in front of the ear might be common during the exanthemata, but he had seen only two cases, and in one there was suppuration, but without injury to the internal structures of the ear. He did not know that it was necessary to use the nasal douche every day on all children, but it was desirable to employ it often enough so that they would become accustomed to it and not struggle when they became sick. All were agreed that lymphoid tissue should be removed when present in sufficient quantity to cause symptoms, but it must be remembered that it was not a substance entirely foreign to the mucous membrane

of the naso-pharynx. Solis-Cohen had cautioned not to remove too much, for the lymphoid tissue was there for some purpose, although we might not yet know what that purpose was. The condition was apt to recur after the operation if the child were allowed to return to the same unhygienic surroundings. As to maintaining a condition of asepsis in the upper air tract, he supposed the reader had used the term in the conventional sense, for a few breaths of air with its contained germs would destroy that condition if brought about by the douche. Probably what was meant was to maintain intranasal cleanliness. An efficient method was the use of a rubber catheter, with a number of fine perforations at the distal end, attached to a syringe, pressure upon whose bulb would throw into the nose numerous fine streams of a solution of salt, borax, and baking soda, about a third of a teaspoonful of each to a pint of warm water.

DR. EMIL MAYER mentioned a case of nasal deformity associated with asthma in a man whose son, aged eight years, suffered from the same conditions, which went to confirm the influence of heredity referred to by Dr. Phillips. When the introduction of the finger into the pharynx was attended by a little bleeding it indicated adenoids. He had never seen hemorrhage follow when the pharynx was healthy, unless the finger were introduced in a rude manner.

To Prevent Chronic Catarrh, Prevent Colds.—DR. FREUDENTHAL said that if we would prevent chronic catarrh we must prevent colds. To do this, children must be brought up differently. In the advice to let them remain out of the house, he would differ from the author only in the suggestion to dress them properly, which was apt to be interpreted as dressing them warmly. Dr. Freudenthal thought the less they were dressed the better. The thought of cleansing the healthy nasal cavity, as he had understood the author to recommend, was to him a terrible one. One might as well insist on cleansing the healthy bladder.

Treats Catarrh Constitutionally.—DR. W. H. MCENROE thought catarrh was a symptom of a constitutional disease, and it was his custom to treat it constitutionally. One of the best remedies was cod-liver oil, and sometimes iodine. As to making local applications to the nose, he was opposed to that, at least as it was usually practised. Salt water was irritating to the nasal membrane, increased the flow, and he preferred to use creolin, which had come to take the place of carbolic acid for this purpose.

DR. F. M. CRANDALL expressed his interest in some of the statistics quoted by Dr. Phillips, as they went to confirm his view that measles was a much more serious disease than the laity and some doctors seemed to think. He would emphasize the advice to keep children out of doors.

DR. LEDERMAN said with regard to cleansing the nose that the nasal mucus itself was germicidal. Colonies of bacteria had been planted in the nose during some experiments, and in a few minutes were all destroyed, as was proven by culture. This went to show that too much cleansing was not the proper thing.

DR. MEYERHOF thought there was usually an underlying condition which favored catarrh in some children, for others in the same family, under the same circumstances, remained well. One-half-per-cent. solution of nitrate of silver was frequently useful, and he had used even four per cent. Ointment of yellow oxide of mercury was serviceable when crusts formed at the entrance to the nares.

DR. DESSAU agreed with those speakers who believed in an underlying constitutional condition, and he emphasized the importance of hygienic measures. He would not say that food was the direct cause of

catarrh, but he thought children who received too much food or that of wrong quality were liable to catarrhal affections.

DR. VIETOR had observed at the seaside that persons who bathed were less liable to colds than others, and those who continued their bathing got well soonest. Swimmers were least liable of all to catarrh.

DR. FERGUSON thought adenoids in the pharynx were a common cause of reflex cough.

DR. H. D. CHAPIN thought the general practitioner was more likely to see the constitutional side of catarrh; the specialist was more likely to apply local treatment. As to adenoids, they could be recognized, but it was not so easy to decide whether in a given case they required removal. Their uniform presence in certain localities indicated a physiological function. In children the introduction of the finger, even in the healthy throat, would cause slight bleeding. When hypertrophied and obstructive, adenoids should be removed. He employed salt bathing, exercise in sunlight, borax and salicylic-acid solution as a nasal douche when necessary.

DR. VAN SANTVOORT said the frequency of cough from posterior nasal disease was something which it had taken him some time to learn. There was only about one case of cough from bronchial trouble to four or five from trouble in the upper air passages.

DR. PHILLIPS said in some concluding remarks that he was glad attention had been called to the constitutional side of the question, for time had permitted him only just to mention it in the paper. In the ear clinic cod-liver oil was one of the most frequent remedies prescribed, along with other tonics. He did not wish to be understood as recommending the removal of more than redundant lymphoid tissue. He did not use the nasal toilet except in disease or acute cold. There was not much danger of overfeeding, but rather of giving food which the child ought not to have. As to cough, nearly all children with adenoids had bronchial catarrh. He thought the cough was due to the latter, and was not reflex. If the adenoids were removed the bronchial trouble would disappear, together with the cough.

Krause's Skin Transplantation in Plastic Surgery of the Face.—DR. JOHN ERDMANN described Krause's method of skin-grafting, related a case in which he had employed it to cover a defect from epithelioma of the face and nose, and mentioned its advantages over Thiersch's method. It consisted in transplanting a piece of skin from some other portion of the body to the freshened area. The graft required to be about a third larger, to allow for shrinkage. The advantages were that it left no cicatrix, the flap resisted destructive conditions, it did not bind underlying tissue, there was no liability to keloid, there was a normal hairy surface. A second case was described in which he had employed the sliding flap to cover a defective area on the face.

Safety from Lightning Stroke in Cities.—A curious fact connected with deaths by lightning has recently been noticed in Europe. It appears that, as compared with the country, towns, and especially cities, possess remarkable immunity from lightning strokes. The statistics which have been compiled on the subject show that between 1800 and 1851 there was not a single death by lightning recorded in Paris, and that only one person out of each million that die in London is taken off by a discharge from nature's electric battery. Between 1851 and 1895 only three persons were struck by lightning in Paris, and only one of these three cases resulted fatally. In Berlin only five persons have been struck by lightning since 1713.—*College and Clinical Record.*

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 1, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

THE resignation of Dr. I. Oppenheimer was accepted.

Practical Points Regarding Senile Insanities, with Special Reference to Prophylaxis and Management.—DR. RALPH L. PARSONS read the paper (see p. 505).

Senile Insanity and Malnutrition.—DR. E. D. FISHER opened the discussion. He thought senile insanity was hardly a distinct form. The essential feature in all these cases was a condition of malnutrition in both the brain and body. The mental deterioration was more due to malnutrition than to actual disease. The pathological state was one of arterial degeneration, either the direct result of old age or of disease in earlier life—nephritis, alcoholism, syphilis. The post-mortem showed few changes—more or less pachymeningitis and increase of cerebro-spinal fluid, or so-called wet brain, together with thickening of the walls of the vessels. Rarely was there evidence of apoplexy or capillary hemorrhage. The condition corresponded closely to what the older writers called serous apoplexy. Dr. Fisher could not admit, in the author's division, an insanity of vigor. When chronic diarrhœa existed, it should not be checked suddenly and entirely, lest it light up the mental symptoms. He had seen only one case in which the insanity was of the form of general paresis. As to prognosis, the symptoms might be improved, but he knew of no cure for senility. The treatment related chiefly to nutrition and stimulation. The patients were better off at home if friends could care for them.

Classification and Treatment Receive Little Aid from Pathological Anatomy.—DR. LANDON CARTER GRAY said there were, in addition to the changes in the arteries so well described by Dr. Fisher, also changes in the lymph vessels and lymph spaces; but, as in other diseases, these were general, and did not account for the various forms in which senile insanity manifested itself, nor furnish a basis for treatment. They were, however, of a nature in accord with the improvement often observed under the influence of stimulants and nutrition. Melancholia in the young was much more controllable than in the aged. In the treatment of melancholia the most important thing was to cut off the expenditure of energy. An abundance of food and stimulants was required. Opium or some one of its alkaloids was efficacious. Massage, gently administered and gradually increased in time to an hour or an hour and a half a day, he had found of decided value. Regarding dementia, which might occur at all periods of life and be primary or secondary, Dr. Gray had found the prognosis better comparatively in the aged than in the young, while the reverse was true of melancholia.

DR. LEONARD WEBER mentioned three cases of senile insanity, in one of which there were varicocele and nightly emissions. While arterial sclerosis might be the fundamental factor in bringing on the senile insanity, he believed functional disturbance of the gastro-intestinal tract had much to do with it.

DR. A. D. ROCKWELL repeated the statement that the nutrition of the brain, effected through the large cerebral arteries, was last to suffer, and said his experience as to the comparative curability of melancholia in the young and old was not in accord with that of Dr. Gray's. He mentioned two cases of cure in the aged.

DR. L. F. BISHOP related a favorable experience with cascara and nitroglycerin in a case under his care

the past summer. The nitroglycerin was given every three hours, one-one-hundredth grain.

Insanity in the Aged Not Always Senile.—DR. A. JACOBI called attention to the fact that there was a difference between senile dementia or insanity and insanity in the aged. The latter might be due to causes acting at any period of life, and which might be relieved permanently. Senile dementia was due to nothing else than the anatomical changes which took place in old age. Atheromatous degeneration was said to begin at thirty-five, and to advance more or less rapidly in different persons until death. Massage was beneficial by stimulating the circulation through its action upon the muscles. Opium was of benefit in many cases, but bromides would do harm rather than good, being more apt to produce anæmia than to cure it. Digitalis should be avoided, because of its contraction of the small arteries.

DR. PARSONS said he always used stimulants.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE—SIR J. LISTER'S ADDRESS—SECTIONS—METROPOLITAN ASYLUMS BOARD—DEATH IN A PADDED ROOM—CARBOLIC ACID—DEATHS OF SIR WILLIAM MOORE AND MR. MERRIMAN.

LONDON, September 18, 1896.

THE British Association has been sitting at Liverpool this week. This association is devoted to science and is the mother of those which hold annual meetings in different localities, many of which take the name of British—the medical being one of its progeny. The full name of the mother is British Association for the Advancement of Science, but it is always spoken of by the short name. How much greater it is than its children may be seen in the attendance, above three thousand, and sometimes it has mustered near four thousand. This year the Earl of Derby accepted the office of lord-mayor of Liverpool in order to do the honors of the city to the devotees of science. He has Sir John Lubbock and Lord Rayleigh in his house party. The leading citizens are vying with each other in their hospitalities. The ladies muster strongly at these gatherings, so that amusements and excursions are much to the front. The healing art, as such, has no home in the British Association, but the sciences on which it is founded are all represented. Whenever scientific men gather, the profession is sure to be represented and its members have often contributed of their best to these congresses.

This year Sir Joseph Lister is president—chosen of course for his scientific work rather than for his surgical position. He is by no means an eloquent speaker. He lacks all oratorical talent, but can demonstrate his views clearly. He read an address which, though well adapted to a semi-popular audience, scarcely does him justice. Due allowance will be made for this by the majority and it will be remembered that no small number went to gaze at the lion of the day rather than to be instructed by his statements. Under the circumstances his subject was well chosen, viz., "The Interdependence of Science and the Healing Art." Thus he was able to bring before his audience the relations of medicine and surgery to modern scientific development. These he illustrated by the application of the Roentgen rays to surgery, Pasteur's researches on fermentation, the antiseptic

system, the isolation of micro-organisms, toxins and antitoxins, phagocytosis, and other allied subjects.

Noticing that this is the jubilee year of anaesthesia, he said "that priceless blessing to mankind came from America," though it had indeed been "foreshadowed in the first year of the century by Sir Humphry Davy." He pointed out that from first to last anaesthesia had been the gift of science. He confessed his preference for chloroform. Vaccination as a topic of the day was judiciously dealt with. Needless to say, his own work could not be ignored in any attempt to give some examples of what medicine has borrowed from science and contributed to it in the last half-century. Equally needless to add that this work was touched with the modesty and reserve of the great scientific investigator and upright skilful surgeon.

The ten sections have been at work for the rest of the week, but a medical journal cannot afford space for their proceedings. The chemical section was presided over by Dr. Ludwig Mond, who in his address related the history of chlorine. The age of the earth was considered by Professor Poulton as president of the section of zoology. "Present and Extinct Flora" was the subject of the address in the botanical section by Dr. N. Scott.

"Music for the Deaf" was the subject of a very interesting paper in the physiological section by Professor McKendrick, of Glasgow. He found it possible to give some appreciation of rhythmical vibrations to deaf people by putting their hands in saline solution through which an electric current from the phonograph was passed. It gave a new sensation to the deaf person.

The metropolitan asylums board is unquestionably a costly one. No doubt its duties are difficult and necessarily involve great outlay. Its resources have up till now been practically unlimited, and like all spending departments thus situated it may have been wasteful or at least extravagant. Ratepayers are delighted to learn that the local government board has rejected the proposal of the asylums board to devote £54,000 to the purchase of a site for its offices. The conscience of those who have their hands in the ratepayers' pockets certainly needs some severe lessons, and this at a time when, in spite of the lavish outlay at Shooter's Hill, the cry still is that the asylums board must build more hospitals to provide for infectious cases.

An inquest was held on Tuesday on a woman, aged eighty-five, who died in the padded room of a workhouse. Some contradictory evidence was given. It was alleged that the nurse had used violence, and the patient had said she "had been ill-using her" and had shown her bruised arms. It was declared that the patient was not violent but only weak. The doctor seems to have acted on the word of the nurse as to her being violent and acknowledged he had not concluded that her mind was affected. He visited her daily and found her always quiet, and did not have her taken back to the sick ward, as she was very ill and seemed comfortable. But the coroner remarked that the space in the padded room was very confined, and the jury made some strong remarks and considered that the case should be investigated by the local government board.

It is said that the proposal to restrict the sale of carbolic acid is now under the consideration of the privy council. It is about time action was taken, as the continually augmenting list of deaths from this poison shows.

Surgeon-General Sir William James Moore, K.C.I.E., H.Q.P., died on the 9th inst., aged sixty-eight. He served in the Indian medical service from 1852 to 1888, and was in the Persian war of 1856-57. His "Manual of Diseases of India" reached a second edi-

tion; his "Family Medicine and Hygiene for India," published under government authority, reached its sixth edition in 1893. After retiring from the service he took up his abode in London and contributed valuable papers to the journals.

Mr. J. J. Merriman, of Kensington, retired from practice about a year ago, when he was presented with a testimonial from his patients of £1,000. This shows how much he was esteemed. He was a type of the best class of general practitioners. He died on the 8th inst. Kensington has had one of the family practising there for above seventy years.

"MALARIAL HÆMATURIA."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of September 19th, in the Clinical Department, appears the report of a case under the above heading, by Dr. Fleming. The case in question was evidently not one of "malarial hæmaturia," but was a case of idiosyncrasy against quinine, which manifested itself by a temporary purpura hæmorrhagica. Quinine idiosyncrasy is frequently met with and in various forms, but perhaps most frequently shows itself as a disturbance of the cutaneous circulation, and this case was unusually severe. On the other hand, "malaria hæmaturia" is not a hæmorrhagic trouble; the morbid condition known by that name in the South, and which I have named lysæmia, is merely blood disintegration. There may be many complications, but dissolution of the red corpuscles from chronic malarial toxæmia is the constant pathological feature. True hæmorrhage does not occur. Even epistaxis is rare.

In the course of an intermittent or a remittent malarial fever, and often without the previous exhibition of quinine, a sudden disintegration of the red corpuscles takes place, and the blood serum becomes saturated with free hæmoglobin, which rapidly stains the skin and sclera an intense yellow and is excreted by the kidneys, coloring the urine, in proportion to the amount, from a pale wine color to a black. "Pokeberry-juice" color is the most common. As before stated, there is no hæmorrhage nor even a hæmaturia, but a hæmoglobinuria. So, from the description given by Dr. Fleming, as well as by the latitude of his patient's residence, we are compelled to exclude lysæmia.

But in answer to his final query, as to whether the cases reported by Dr. Bush may not have been pure malarial fevers complicated by treatment, the answer is, No and Yes. They were not pure (simple) malarial fevers, but they were complicated by treatment, if quinine had been administered previous to Dr. Bush's institution of a more correct treatment. They were cases of lysæmia, and when that condition exists the administration of quinine increases the blood disintegration, irritates the kidneys, and frequently causes, from said increase of broken-down corpuscles and from said irritation, a blocking up of the uriniferous tubules, suppression of urine, uræmia, and death.

There seem to be some rare exceptions to this rule, but in the present state of our knowledge it is far safer to abandon the use of quinine at the first symptom of lysæmia, but not before; for while the use of quinine may be disastrous after the onset of so-called malarial hæmaturia, the fact of that morbid condition's presence is certain evidence that quinine has been neglected when first needed. If every person in condition to need quinine were to take the same at the first warning, and take it intelligently, there would never be another case of lysæmia.

THE THEORY OF ELIMINATIVE TREATMENT OF TYPHOID FEVER.*

BY W. B. THISTLE, M.D., L.R.C.P. LOND.,

TORONTO, CAN.,

ASSISTANT DEMONSTRATOR OF ANATOMY, UNIVERSITY OF TORONTO; LECTURER ON NERVOUS DISEASES AND DISEASES OF CHILDREN IN THE WOMAN'S MEDICAL COLLEGE; PHYSICIAN TO THE VICTORIA HOSPITAL FOR SICK CHILDREN, TORONTO.

ALTHOUGH the practice of administering purgatives freely and frequently throughout the entire duration of typhoid fever has extended widely in this country since the publication of my first paper on "Eliminative and Antiseptic Treatment of Typhoid Fever," in the *Canadian Practitioner* for April, 1893, and the objection that great danger is associated with such a course is now seldom heard, yet there still exists much misconception regarding the ideas which underlie this plan of treatment. This misapprehension is mainly due to a faulty appreciation of what is meant by "elimination," the term being made to indicate only the clearing of bacteria from the intestine, the far-reaching effects of purgatives on the body generally being altogether ignored. The misapprehension I refer to is well illustrated in the inaccurate report of the eliminative and antiseptic treatment of typhoid which appears in the recent edition of a well-known work on the practice of medicine.¹ In addition to the common mistake, the writer of the book asserts that this treatment is based on erroneous ideas of the pathology of the disease. Eliminative treatment is, in the paragraph referred to, said to depend on the erroneous idea that the specific bacteria are confined chiefly to the intestine. Continuing, the writer of the book makes the positive statement that the specific bacteria are not present in the intestine until the ninth day of the disease. It is also pointed out that the specific germs are found in the spleen and in other parts of the body, the reader being led to infer that the advocates of the eliminative treatment had failed to appreciate that fact.

In a paper devoted to the theory of eliminative treatment I hope to make more apparent the ideas upon which it is based and to indicate more clearly the objects to be attained by the continuous administration of purgatives throughout the disease; but more especially do I wish to combat the assertion that this treatment is based on an erroneous conception of the pathology of the disease.

I shall at the outset and at the risk of being tedious briefly set forth the eliminative and antiseptic plan of treatment, in no way varying from that which appeared in the papers published by me in the *MEDICAL RECORD* of March 10, 1894, and September 14, 1895. In the papers referred to, I subscribed to the view that typhoid fever is a condition in which prolonged poisoning occurs, the toxins being produced by certain bacteria which enter the body and flourish mainly in

the alimentary canal, but which are also found in the glands of the intestinal wall, in the lymphatic nodes of the mesentery, in the spleen, and less frequently in the lungs and other viscera. Their original location, however, is the intestinal canal; that is, they are first free in the intestine, but are afterward to some extent carried by the absorbents into other parts of the body. Wherever located they, as a necessary part of their life, produce a toxic substance, which in turn produces the phenomena of the disease. Wherever the bacteria are, there of course will be the toxins which have been elaborated as a result of their activity; so that in the course of the disease the absorbents would carry toxins from the bacteria in the intestinal contents; from the colonies of bacilli within the lymph glands in the intestinal wall and mesentery, while those generated by the bacilli which have reached the spleen or are located in other viscera will be thrown directly into the circulation.

In the former papers referred to, I held to the view that the toxæmia of typhoid is due to more than one form of bacillus; that while everything points to a specific bacillus, such as that described by Eberth, yet it is impossible to ignore the extreme likelihood of a portion of the toxæmia being due to poisons produced by other bacteria, notably by the bacillus coli communis. In support of that view I cited the facts, that under certain conditions the colon bacilli do become exceedingly poisonous; that they produce the toxin which leads to fatal results in peritonitis; that it has been pointed out that wherever the intestine is injured these bacteria take on virulent properties.² There is also the probability that the bacillus coli communis becomes virulent as a result of association with Eberth's bacillus.

I also urged that in addition to poisons produced by Eberth's bacillus and by the colon bacillus, some portion of toxæmia must be attributed to putrefactive and other bacteria in the intestine.

Throughout the course of the disease there is a continual augmentation of the toxæmia by absorption from the intestine, and from accessions of quantities of poison produced by the colonies of bacilli in the spleen, mesenteric glands, or Peyer's patches.

As to the manner in which these toxins affect the system I quoted Woodhead³ to show that, like many substances spoken of as poisons, they had what might be termed a constitutional and also a local action. In the circulation they bring about widespread disturbance of function, e.g., fever, headache, vertigo, delirium, coma, etc., and where gathered together or concentrated at one point irritation of tissue occurs, with the usual phenomena of increased rapidity of cell multiplication, increased vascularity, and increased exudation from the vessels into the surrounding tissues. If concentrated still further, or if the period of contact be extended beyond a certain point, increased activity in the tissues is replaced by stagnation and death of the part, with subsequent casting off of the necrotic portion.

While there is undoubtedly a great difference in the virulence of epidemics, as well as a difference in the susceptibility of individuals, yet in a given case the symptoms increase in severity in proportion to the

* Read before the meeting of the Canadian Medical Association, Montreal, August 27, 1896.

quantity of toxins in the system. The symptoms taken as a whole indicate the degree of toxæmia.

Turning now to the most recent English work on medicine, I find that the writer on typhoid fever, Professor Dreschfeld, of Manchester, believes Eberth's bacillus to be the primary cause of the disease, but that many of the symptoms and much of the toxæmia are due to the colon bacilli and to other germs.

He also gives, without comment, the results of investigation by Pisenti and Biancho-Mariotti to determine the relation between the typhoid bacillus and the bacillus coli.

1. On simultaneous injection into animals of cultures of bacillus typhoides and bacillus coli (which latter had been proved to be inactive), bacillus coli increased in virulence so as to act like any virulent bacillus typhoides on animals.

2. If sown on gelatin mixed with filtered cultures of bacillus typhoides, bacillus coli also gained in virulence, owing to the typho-toxin acting on bacillus coli.

3. Healthy intestinal epithelium hinders infection from the intestine, but if Peyer's patches undergo changes, this defence is in abeyance.

Filtrates from typhoid cultures exert an influence on Peyer's patches, so that in typhoid fever the toxin in the blood alters the Peyer's patches and thus bacillus coli enters the body and adds to the virulence of the typhoid infection.

4. With very virulent cultures of bacillus coli, results were produced (such as thermometric curves, for instance) similar to those obtained by very virulent bacillus typhoides, and animals could be thus immunized against bacillus typhoides. At the same time the experimenters refrained from any expression of opinion as regards the identity of the two.

Regarding the mode of infection, Professor Dreschfeld believes that the bacilli "reach the alimentary canal, multiply, penetrate into the mucous and sub-mucous coats, invade the lymphatic tissues, and pass thence through the lymph channels into the mesenteric glands. Some of the bacilli reach the blood and pass to internal organs, principally the spleen. The bacilli produce various poisons, at present hardly known; some of these have a pyrogenetic action and thus produce the fever. As a result of their irritant action and that of their products, we get the intensely inflammatory signs in the intestine leading to necrosis."

I have quoted sufficient to show the ideas regarding the pathology of typhoid adhered to in this most recent work on medicine. I submit that these ideas as to pathology and mode of infection in typhoid are identical with those upon which I based eliminative treatment, as can be shown by reference to my published papers on the subject. In addition, however, I questioned the correctness of the very general statement that the specific bacteria are not present in the intestinal contents during the first nine or ten days of the illness. I maintained that, having in view the very great similarity between bacillus typhoides and bacillus coli, and the failure to find methods of differentiation which could be considered at all reliable, that simply because bacteriologists working with uncertain methods had not found Eberth's bacillus before the ninth day, the assumption that this bacillus is absent from the intestinal contents before the ninth day was not justifiable. I argued that since there can be no doubt of their presence and multiplication originally in the intestine before infection of the glands—for how otherwise can the simultaneous invasion of Peyer's patches for several feet of the length of the intestine be explained?—and since there is no difference of opinion regarding their presence in the intestine after the ninth day, the dogmatic assertion of their absence during the first nine days is

unreasonable. More than that, if adhered to, it led to the absurd contention that the bacilli enter the intestine, multiply there, penetrate into the intestinal walls over a large extent, the process occurring without symptoms of any kind, but when the last specific germ has passed from the intestine into the body, then, and not until then, are there signs of illness. Such a theory is manifestly unreasonable, yet, unless it be maintained absolutely, the contention that the specific bacilli are absent from the intestine during the early period of the disease must be abandoned. In other words, the process of invasion of the glands is coincident with the earlier symptoms of toxæmia.

This is the only point in which the ideas expressed by me in the papers on eliminative treatment differ from those set forth by Professor Dreschfeld. But he does not assert the absence of Eberth's bacillus from the fæces in the early period; he merely states that they have not been found there during that time. He appends, however, a paragraph pointing out that since his article was in press, the new method of Elsner, which appeared "to fill the long felt want of easily isolating the bacillus of typhoid and to distinguish it from the colon bacillus," had been discovered. By this method, Elsner was able to easily separate Eberth's bacilli from the fæces in fifteen out of seventeen cases in the various stages of the disease. The two cases in which he failed to obtain them were entering upon convalescence and the temperature was normal.

Elsner's method was tested by Brieger⁶ in eleven cases and by Lazarus⁷ in forty-one cases, and his results were confirmed.

Brieger found Eberth's bacilli in the dejections of typhoid patients while the symptoms were still obscure.

In repeating Elsner's examinations, in forty-one cases Lazarus found that the specific bacilli disappeared from the dejections with the beginning of convalescence, but that in the case of relapse they were again found in the fæces.

Thus it seems that what I argued must be the case in my article in the MEDICAL RECORD, September 14, 1895, has actually been demonstrated.

That the tests made use of prior to Elsner's method for the differentiation of bacillus typhoides from bacillus coli were not to be relied upon is shown by investigations carried on by Professor Dreschfeld and Mr. Robinson in the laboratory of Victoria College, Manchester. They found that some apparently typical colonies of Eberth's bacillus produced gas in saccharine media, others did not. Of those which produced no gas, some gave the indol reaction, and three did not. These three coagulated milk.⁸

My great error according to the author of the American work on the practice of medicine to which I referred in the beginning of this paper was in believing the specific bacilli to be present in the intestine during the early period of the disease. I submit again that, in the light of what has been demonstrated by Elsner and corroborated by Brieger and Lazarus, the error is not mine.

I asserted at the beginning of this paper that there exists much misconception regarding the objects to be attained by the continuous repetition of purgatives throughout the disease. I also expressed the opinion that the misapprehension arose chiefly because elimination is taken to mean simply the clearing out of the specific bacteria from the intestine, whereas a much wider process is indicated by the term "eliminative"—how much wider I hope to show when we come presently to the effect of purgation in typhoid.

However, before entering upon the treatment, there are some fundamental facts which it is necessary to keep prominently in view in order to appreciate the logic of the eliminative treatment.

1. There is the constant augmentation of the toxæmia; the toxin produced by bacilli in the intestinal contents, and that elaborated by the colonies located in Peyer's patches and in the mesenteric glands, are constantly being conveyed into the general system. Toxins produced by colonies in the spleen or in other viscera will reach the circulation at once.

2. That during the course of the disease bacilli, both specific and bacillus coli, as well as toxins are carried from the intestine still further to increase the number in Peyer's patches, mesenteric glands, and spleen, and to increase the toxæmia.

3. That death comes in typhoid fever in two ways, leaving out of consideration accidents such as epistaxis, etc., either by the excessive accumulation of toxins in the body or by the excessive local action of the toxins on particular tissues. Roughly, it is said that eighty per cent. of the mortality of typhoid is due to toxæmia; that is, the constant augmentation of poison in the body, either directly by overcoming the vital centres, or less directly by producing exhaustion through prolonged interference with the functions of nutrition and repair, proves fatal.

The remaining twenty per cent. of the fatality includes, of course, the rare accidents and complications, but is chiefly made up of the cases that result fatally owing to the excessive local action of the toxins on particular tissues. By far the greater part of this is due to hemorrhage and perforation, two accidents incidental to necrosis. Necrosis occurs with so great frequency in Peyer's patches because of the facility with which bacteria, specific and others, and also toxins, are carried from the intestine to the glands. The colony originally in possession increases rapidly, elaborating at the same time toxins. Moreover, throughout the disease there is a constant reinforcement, owing to carriage of bacteria and toxins from the intestine. At first the gland is swollen, owing to the attempt of the tissues to destroy the intruders; but finally, in the case of the glands that ultimately become necrotic, the tissues are unable to resist the prolonged action of the ever increasing toxins and death of the part occurs. Let us now notice the defensive measures against the condition described.

There are the channels through which toxic substances leave the body.

In the order of their importance they are:

1. The bile. By way of the biliary secretion much of the toxins escapes from the body into the intestine and from there is carried out. So much of the toxin elaborated in ordinary condition of health escapes with the bile that Bouchard estimates the toxicity of bile as nine times greater than the toxicity of urine.

2. Next to the bile as a channel for the elimination of toxins comes the urine.

3. The serous secretion from the intestine carries with it whatever poisonous substances may be in the circulation and the body is relieved of so much toxin, just as it would be if bleeding instead of purging the patient had been resorted to.

4. In addition to these three channels, toxin of course escapes by the breath and by the skin.

A further defence is found in the resistance and aggressive action of the tissues themselves. Indeed, in cases that recover, the bacilli in the body must be destroyed by the tissues, excepting of course those that escape by the urine. Just here it may be noticed that the aggressive and defensive action of the tissues is in inverse ratio to the extent of the toxæmia.

The plan of treatment which I in 1893 brought forward as the "eliminative and antiseptic treatment of typhoid" consists in the administration of frequent doses of purgatives throughout the entire illness. It is also considered of primary importance that purga-

tion be secured as soon as possible after the patient comes under notice.

The purgative medicines chosen are those that act on the upper and smaller intestine. Perhaps the most satisfactory is the combination of calomel and salines. The calomel may be given in several doses, say of a half or one-grain, and followed in several hours by a saline, magnesium sulphate or sal Rochelle in half-ounce doses. However, other purgatives may be given—cascara, Seidlitz powders, Carlsbad salts, compound cathartic pill, etc. The quantity of the dose and the frequency of the repetition must be determined by the necessities of each case.

With the employment of purgation is associated the use of antiseptics. My experience is with salol chiefly, and my practice is to give it in ten-grain doses every three or four hours. I have pointed out before in the articles above referred to, that antiseptics may be given in much larger doses and with greater freedom from the occurrence of symptoms due to the antiseptic, if associated with the frequent administration of purgatives. To compensate for the withdrawal of so much fluid from the body by so frequent purgations, as well as to dilute and facilitate the elimination of poison through the kidneys, the ingestion of large quantities of water is enjoined. Coming now to the purpose of this treatment, it is obvious concerning the antiseptics and the giving of large quantities of water.

The purpose of giving purgatives in the way I have described is:

1. To interrupt the process of infection; that is, by sweeping out the intestine to clear away bacilli, specific and non-specific, and also toxins which would otherwise go to increase the number of bacilli in the body and to increase the existing toxæmia.

2. To counteract at frequent periods the continuous augmentation of toxins in the body by carrying away the toxic bile poured into the intestine, which if not carried away is again taken up and returned to the system.

3. To further deplete the volume of toxins in the body by causing a free secretion into the intestine, bringing with it toxins in solution in the body fluids.

4. The constant clearing of the intestine must lessen the extent of the local lesion, because it cuts off the base of supply from which bacilli and toxins are carried to Peyer's patches to reinforce the bacilli and toxins already in possession. It is apparent, too, that the earlier this is resorted to, the better for the tissues in Peyer's patches. Thus, while on the one hand there is a continual production of toxins in the body, on the other by the frequently repeated administration of purgatives we endeavor to eliminate these toxins in sufficient quantity to keep the total volume of poison in the body below a harmful point until the period of immunity is reached. In like manner, keeping the intestine clear limits the local lesion in the intestinal glands.

A frequent mistake in carrying out this treatment is in supposing spontaneous action of the bowels to contraindicate the use of purgatives. Such is not the case, for it is well known that the diarrhœa is most frequently owing to catarrh of the colon and to toxæmia. Thus, while the bowels may be acting many times a day, yet little in the way of elimination of toxins is accomplished, the toxic bile in the upper intestine and the bacterial collections in the ilium remaining undisturbed. Indeed, in this instance, as in the mycotic and irritant diarrhœa of children, the flux is best controlled by giving a purgative.

Returning to the details of treatment, I have before pointed out that it is of the greatest importance to secure elimination by the bowels as speedily as possi-

ble, in order to cut short at the earliest possible period the process of infection.

Because the case appears to be a mild one is no reason for withholding treatment, for the case that appears mild may in ten days' time, by the process of gradual accumulation which I have described, show symptoms of the most profound toxæmia. In many cases, too, in which the symptoms are not pronounced, the local lesion may be so severe as to prove fatal.

It has been objected that so frequent purgations must do harm by carrying out useful bacteria from the intestine.¹ There is no ground for such a supposition, for experiments to determine that point show that a perfectly sterile intestine in no way interferes with health.²

ON THE PREPARATION OF BLOOD FOR MICROSCOPICAL EXAMINATION.

By HENRY G. PIFFARD, M.D.,

PROFESSOR OF DERMATOLOGY, NEW YORK UNIVERSITY; CONSULTING SURGEON TO THE CITY HOSPITAL, ETC., ETC.

THE proper manipulation and mixing of the blood with diluents to facilitate the accurate counting of the different corpuscles is fully and properly described in various text-books, and accompanies the Thoma and other forms of apparatus that have been devised for the purpose. I have nothing to add to the published descriptions.

The various technical points to be considered in the examination of fresh undried blood are also to be found in the text-books, but are given in most elaborate detail in Hayem's extensive Treatise on the Blood. I cannot from my present knowledge improve on them.

There is, however, another branch of blood examination which at the present time is exciting an increased and well-merited interest. I allude to the preparation and examination of blood spread in a thin layer and dried on cover glasses. This, too, is treated of in more or less detail in the text-books and in special writings, but, I regret to say, is usually presented in a faulty manner. Instead of the best technique being given, it is usually the worst: important points not being alluded to, or directions are given that tend to obscure rather than elucidate the objects of the research. This criticism is intended to apply particularly to the German text-books and to the writings of American laboratory workers who learned their microscopical technique at the continental universities, and who in their teachings here still follow their early practices.

I will admit in advance that no matter how carelessly you manipulate the blood or conduct the examination, some facts can be ascertained; but if you desire to exhibit any given specimen in the clearest and most distinct manner, and to learn the greatest number of facts concerning it, the strictest attention should be given to each and every important detail, both from a histological and optical standpoint.

It will certainly be conceded that it is better to do a thing well than to do it negligently, and if the best results are to be obtained the best technique must be followed, even should it prove more expensive or

more troublesome than an inferior one; and yet I venture to say that the majority of blood examinations are not made under the most favorable conditions even by those who know or ought to know better.

Errors in technique naturally lead to erroneous observations, and these, in turn, to false reasoning and conclusions, and it is to this more than any other one cause that we have laid before us so many contradictory statements.

Blood films are studied from several standpoints and with several distinct objects in view. These are chiefly: (1) To determine the presence or absence of malarial plasmodia; (2) to ascertain the presence or absence of the eosinophil, neutrophil, or basophil granules of Ehrlich; (3) to observe changes and abnormal appearances in the leucocytes and red corpuscles; and (4) to determine the presence and kind, or absence, of micro-organisms. In all of these cases the manipulation is substantially the same, with the exception of the stains to be employed.

It is this technique which I desire to describe in the fullest detail, and with special reference to (1) the slide, (2) the cover glass, (3) the needle, (4) the forceps, (5) the spreading of the film, (6) the fixing and dehydration of the corpuscles, (7) the staining, (8) the mounting, and (9) the optical apparatus, and especially the condenser and objective.

Competition during the last few years has reduced the price of slides to an almost ridiculously low figure, but, unfortunately, this reduction has been accompanied with a deterioration in the quality of those offered by most of the supply houses. The glass, cut roughly to size, is imported, but afterward is ground and finished in this country so carelessly that a considerable proportion are smaller than they should be, and with ends that are not always square. The most satisfactory slides that I have been able to obtain are those furnished by Zeiss, at three and a half marks per hundred. These are cut true to size (76 mm. by 26 mm.) are of good glass, and easily cleaned for use with a drop or two of alcohol and a piece of Canton flannel. Zeiss also supplies slides of plate glass at double the price above mentioned, but these it is almost impossible to clean with either alcohol or acid. The slides chosen should be of medium thickness. Very thin ones were formerly of service when attempting difficult resolution with extremely oblique mirror illumination. With substage condenser, however, extreme thinness of the slide is not only unnecessary but undesirable, especially in high-power work. The majority of modern microscopes that pretend to any degree of excellence are provided with substage condensers, either N. A. 1 achromatic, or N. A. 1.20, or 1.40 Abbe. Now, these apertures are possible only when there is a layer of cedar oil between the condenser and the slide. The principal microscope makers list their condensers as having the apertures mentioned, but not one of them, so far as I am aware, has the honesty to state that these apertures exist only when they are used with oil immersion, and that when used dry, as is usually the case, the numerical aperture is very much less. If, now, the observer desires to employ an immersion objective of high aperture and to work it at its best, he must put oil on the condenser and focus it for critical illumination. If the slide is an exceedingly thin one, in bringing up the condenser to keep the oil in position he will project the flame image above the plane of the object under examination. If the condenser be now depressed so as to make the flame image coincide with the object, the oil is apt to run out, especially if the microscope be inclined. The condensers are constructed to work with slides of medium thickness, and such slides are the only ones that should be used.

In the selection of cover glasses, even greater care

should be employed. The dealers offer both square and round covers in various sizes and thicknesses. The square are cheaper than the round, and for this reason are used by many. Little economies of this sort may be thought well of in German and French laboratories, but should never obtain a footing among workers whose aim should be to spare neither pains nor expense to do their work in the most perfect manner. A hundred slides properly prepared and mounted will prove of far greater value to the operator and to the world than a hundred and fifty in which the operations have been conducted in an unskilful and slovenly manner. Square cover glasses should never be used in the preparation of blood films: First, because it is exceedingly difficult to obtain a good smear; and, second, it is next to impossible to mount them in a satisfactory manner for permanent preservation.

The most convenient size of round glass will be either $\frac{3}{4}$ ", or 18 mm. American dealers supply the covers in four classes, graded according to thickness, namely, Nos. 0, 1, 2, and 3. The first two are altogether too thin for general use, and should not be purchased under any consideration. A great deal of blood work can and had best be done with dry lenses, and the non-adjusting dry lenses in common use are corrected by their makers for a certain definite thickness of cover glass; and if a thinner one is employed, the image obtained will be imperfect, or "under-corrected," as the opticians say.

In order that this matter may be clearly understood, I will enter a little at length into the optical aspect of the case. The image formed by any lens is the resultant of a vast number of images formed by the different zones of the lens from near the axis to near the margin. If, now, these different zone images are all brought together at a common focus, the resultant image is clear, brilliant, and well defined. If, on the other hand, the images from the marginal zones come to a focus before the images from the zones nearer the axis, the resultant image is said to be "under-corrected," and will be found less brilliant and distinct than it should be. In fact, an under-corrected image is a composite, consisting of a vast number of separate images lying in different planes, and each of them differing in size from the others; those lying lowest being the larger. Under these circumstances, sharp definition is entirely out of the question. To test this experimentally, take a No. 7 Leitz objective which is corrected for a cover-glass thickness of 0.17 mm., and procure some cover glasses of that thickness. On these covers prepare some blood films. With the microscope in a vertical position, put a clean slide on the stage, and on this lay the cover, film side down, without balsam or any other medium intervening. If, now, the illumination is properly arranged, an exquisite image of the corpuscles will be seen. Next raise the objective and turn the cover over so that the corpuscles shall have no glass over them. If we again examine them, we shall have an image that is under-corrected to an intense degree. If, now, a blood film is spread on a cover glass, say 0.05 or 0.10 mm. in thickness, and examined film side down, the image will still be under-corrected, though not so greatly as before. With oil-immersion lenses of moderate aperture, N. A. 1.20-1.30, cover-glass thickness is of little moment. So, also, if dry adjustable lenses are employed. To obtain, however, the best results with the ordinary non-adjusting dry lenses, the thickness of the cover glass used should be that for which the lens is corrected. Most objectives of this sort are corrected for covers of from 0.17 mm. to 0.20 mm., each maker being a law unto himself in this respect.

The cover-glass thickness will be found to play an important part in blood examinations, and I would strongly advise any one who desires seriously to take

up this work at once to procure an instrument for measuring the thickness of the covers. Zeiss supplies such an instrument, and so also do Bausch & Lomb. The former I have never seen; the latter I use with the greatest satisfaction. If the cover-glass gauge be applied to half an ounce of No. 2 covers, the operator will probably be a good deal surprised at the varying thickness of the glasses, some being not thicker than 0.07 or 0.08 mm., while others will run up to nearly 0.30 mm. A half-hour will be well spent in sorting these over, putting each thickness into a small envelope by itself. Out of the half-ounce perhaps ten or twelve per cent. will be found of the exact thickness best suited to your objective: but if an objective of medium aperture (e.g., Leitz No. 7, N. A. 0.85) is to be used, a little margin in the thickness may be allowed, say from 0.15 to 0.20 mm., and the half-ounce will yield perhaps fifty per cent. of covers coming within this range. The No. 3 covers, though costing less per ounce than the No. 2, will yield a much smaller proportion of available covers. Zeiss supplies most admirable covers, selling only those which fall between 0.15 mm. and 0.22 mm. At a slight advance in price, he will supply any given thickness that may be desired. Such covers, however, are not carried in stock. I believe, by any New York supply-house, but will be imported on special order by Eimer & Amend; and I have for a considerable time procured most of my covers in this way.

The next step is the proper cleaning of the covers. A small glass dish should be partly filled with battery fluid (water, nine ounces; bichromate of potash, one ounce; sulphuric acid, one ounce), and into this the covers should be dropped, one by one, so that both sides of the cover may be wetted by the fluid. After remaining in this for twenty-four hours, the acid is poured off and the covers are flushed *en masse* two or three times with water. Then each should be taken separately and dropped into a dish of distilled water, from which they are to be transferred, singly as before, to alcohol (preferably pure methylic¹). A most convenient receptacle for the alcohol and covers is a one-ounce, square, screw-capped bottle, in which they may be kept until needed for use.

A very convenient instrument for drawing the blood is a small, straight, surgical needle, several of which should be kept in a vial of alcohol until needed. For a couple of years or so I have used needles made from an alloy of one part of iridium and two parts of platinum. When required for use the needle is sterilized at a white heat immediately before and after use. The blood may very conveniently be taken from the tip of the finger, though some writers insist that it is better to draw it from the lobe of the ear. In either case the part should be thoroughly cleansed.

Two pairs of forceps are required. One should be of the self-closing variety, with flat, broad points, and with spring sufficiently stiff to hold the cover firmly against moderate traction. The other pair may be any sort that will hold the cover nicely.

A sufficient number, say six or eight, of the covers are removed from the alcohol, thoroughly dried, and laid upon any suitable support, projecting a little beyond it. One of the covers is seized with the self-closing forceps and placed ready at hand. The puncture is then made, and another cover is quickly taken with the second forceps and applied to the droplet of blood as it issues from the wound. The second cover is then laid on the first, and the blood spreads out between them. A common fault with beginners is taking up too much blood; but this will be corrected after a little practice. As soon as the film is spread,

¹ I do not refer to the stuff called "methylated spirits" in English writings, as the latter is ordinary ethylic alcohol mixed with common wood spirit.

the projecting edges of the upper cover are taken between the thumb and index finger, and the covers are gently slid apart, care being taken to keep them parallel until entirely separated. The two covers, with films up, are now laid on a piece of paper to dry, and a second pair are prepared in the same manner. If more than four covers are desired, a fresh puncture should be made. As soon as the films are dry they may be placed in a small envelope (say $2\frac{1}{2}$ " by $1\frac{1}{2}$ "), properly labelled. If stored in a dry place they will keep unchanged for a long period. It is better, however, to fix them immediately. If water or any staining fluid were applied before fixing, most of the corpuscles would be washed off the cover, and from those that did remain the haemoglobin would be removed, leaving only the almost invisible stroma.

Ehrlich, who was the founder of one branch of hematic microscopy, declared that the corpuscles were best fixed by heat, and advised that the covers be laid on a metallic plate supported over a lamp, and be subjected for several hours to a temperature of 120° to 130° C. Some operators simply flirt the cover a few times through a lamp flame, just as they would in fixing bacteria. This procedure is to be condemned at the outset. However well or ill it may serve for bacteria, it should not be practised in connection with blood covers. If there be absolute necessity for haste, the corpuscles may be fixed by subjecting them for a few minutes to the fumes of a two-per-cent. solution of osmic acid, or they may be placed five, ten, or fifteen minutes in absolute alcohol, or a mixture of this with an equal volume of ether. My own experience, however, with human and other mammalian blood, as well as with the blood of birds and reptiles, leads me decidedly to prefer fixing by heat rather than by any of the other methods that have been employed.

Ehrlich's metal plate, however, is troublesome and not altogether satisfactory. If the operator has gas at his command, he will find a small Fresenius oven much more satisfactory. This should be fitted with a Reichert or Dunham thermostat and a centigrade thermometer. The Dunham is said by those who have used it to be a much more satisfactory appliance than the Reichert. I have used only the Reichert, and, finding it troublesome to manage, abandoned gas in favor of electricity. For the past year or more I have used an electric heater controlled by a rheostat, and am able to obtain a much closer adjustment and regularity of heat than I had previously been able to do with gas.

The covers are heated gradually to about 125° C., and then maintained at this for an hour or more. When the covers are taken from the oven, they are allowed to cool gradually and thoroughly before staining.

Those who desire to know in how many ways blood may be stained and for what purposes, may consult the pages of Friedlander: or, if more convenient, the recent translation of von Kahliden's "Methods of Pathological Histology."

For most purposes, however, double staining with eosin and methylene blue is all that is necessary. Grüber supplies three varieties of eosin, but the "soluble in alcohol" is the only one adapted to our present purposes. Of this dissolve one grain in twenty-five cubic centimetres of alcohol, and after it has stood twenty-four hours add an equal quantity of distilled water. The methylene blue to be used should be Grüber's "rectified." Most authors recommend Loeffler's alkaline solution. This stains the nuclei of the leucocytes deeply, but is also apt to stain the red corpuscles and platelets. I prefer, therefore, to dissolve 0.50 of the stain in fifty cubic centimetres of a five-per-cent. solution of formalin. This gives an intense and brilliant nuclear stain without affecting the other elements, unless its action is unduly prolonged.

When ready to stain the covers, place them film up on a plate of glass, and cover each with the eosin solution. Leave this on for two or three minutes, and wash off with distilled water. When the covers are dry, apply the methylene-blue solution in the same manner; and when this is washed off and the covers are thoroughly dry they are ready for preliminary examination.

Arrange the microscope vertically, with a clean slide on the stage, and place on it the cover, film down and without any intervening medium. Alongside of it, if you choose, mount another cover in balsam and compare the two. The difference between the two is so striking and absolutely in favor of the dry cover, that I venture to say you will never again use balsam for this purpose. This examination must, of course, be made with a dry lens. A No. 7 Leitz answers very well, but a $\frac{1}{2}$ " or $\frac{1}{10}$ " objective, with a numerical aperture approximating 0.90, is still better.

If the examination with the dry lens does not give all desired information, and you wish to examine further with a higher-power immersion, it will be necessary to attach the cover permanently to the slide.

Every book and every writing on this subject that I have seen advises that the cover be mounted in balsam. This advice and practice are decidedly and emphatically wrong, and I am amazed that men who have devoted so much time to the subject, and who certainly ought to know better, still continue to pursue a method that certainly destroys one-half the value of their work.

If you desire to mount blood covers to the best advantage, the first step is to procure a turntable. Centre the slide carefully on this, and spin a thin ring of shellac or other suitable cement, corresponding to the size of the cover; a second coat may be applied a few minutes later. Prepare a number of slides in this way, and leave them for twenty-four hours or more to dry.

When the slides are ready for use, take one and hold it over a flame for a moment or two to expel all surface moisture and to soften the cement a little. The cover in like manner should be flirted over the flame, to expel all moisture from its surface. It is then applied to the cement ring, care being taken to have contact at all points of the circle. When entirely cold, a fresh ring of cement may be spun around the cover, so as absolutely to seal it at every point. The slide is now ready for examination in any manner, and with any dry or immersion lens.

It matters not whether you are studying the changes in the leucocytes, hunting up the various granules of Ehrlich, or searching for the elusive plasmodia, the optical picture will be vastly superior and much more instructive than any you can obtain in balsam mounts.

Before closing, I desire to say a few words about the substage condensers. If circumstances restricted me to the use of a single condenser for all purposes, I would choose an achromatic N. A. 1, which may be obtained of excellent quality from Zeiss, Bausch & Lomb, Watson of London, and other makers, costing perhaps ten or twelve dollars more than the customary "Abbe." With dry lenses, except those of the very widest aperture, I should use it dry, that is, without oil between the condenser and the slide. By so doing you impair the nominal aperture about one-third, and throw it a little off its corrections; but even then it will be better than any of the Abbe construction. If used in connection with immersion lenses, oil contact should be used, so as to secure the full aperture. If circumstances permit the expenditure, an additional achromatic of N. A. 1.30 to 1.40 should be added; and for low-power work, an achromatic of low aperture, say N. A. 0.60 to 0.75. I know of but one optician that offers such a low-power condenser, and regret to

say that I have not found it satisfactory. In regard to the Abbe condensers that are in such general use, it may safely be said that they are a vast improvement on simple mirror illumination, that was almost the sole dependence before Professor Abbe introduced his simple device. The low cost has undoubtedly been the chief means of its wide introduction, but as an optical instrument of precision it is decidedly inferior to an achromatic of approximate aperture.

Through force of circumstances, fully nine-tenths of the laboratory workers employ diffuse daylight as an illuminant, and for the great mass of work to be done it is amply sufficient and satisfactory; but for the most delicate work a well-arranged artificial light is preferable.

At the present time the blood offers one of the most inviting fields of investigation, as an aid both to diagnosis and to therapeutics; and I cannot too strongly urge on those who design to take it up to pay the strictest attention to what at first may appear to be unimportant technical details.

10 WEST THIRTY-FIFTH STREET.

RHEUMATISMUS NEONATORUM.*

By R. ABRAHAMS, M.D.,

DISTRICT PHYSICIAN TO THE MOUNT SINAI HOSPITAL, NEW YORK.

ACUTE articular rheumatism, in early infancy, is regarded by all systematic writers as an exceedingly rare occurrence. Cheadle¹ mentions two cases referred to Senator, and credited by the latter to Stäger and Windeshofer, in which two infants, one four weeks and the other twenty-three days old, were affected with acute rheumatism. Strümpell,² in discussing the etiology of the disease, cites "a single interesting case" which he met in Leipsic. In this instance, the child was only a few days old, and suffered from "multiple purulent arthritis." On looking over the literature of acute rheumatism in childhood, I came across two more instances of the disease reported as occurring in two infants, one twelve hours old,³ and the other three days old.⁴ I looked in vain for more records of cases. If any escaped my study and scrutiny, I shall be grateful to learn of them. If we accept the traditional causation of rheumatism, viz., exposure to cold and hereditary tendency, there certainly can be no reason why a good many of our newly born should escape it. For the diathesis is admittedly prevalent, and as to exposure, who knows better than the little newcomer the cruel extent it is subjected to by the daily oiling, soaping, and washing, and bathing? With all that and in spite of that, recorded histories of rheumatic fever in the very young are so very, very few. To my mind the scarcity of such observations seems to be due to a lack of care on the part of the medical attendants. For instance, when the baby cries, the scion of Hippocrates readily submits to the supposition of the nurse or of a sympathetic neighboring woman that it must have colic; the drawing up of its tiny limbs is but infallible light on the diagnosis. The possibility that the infant may be suffering from painful ankle or knee joints may never appeal to his deep-seated centre of thought, and yet it may just be this and nothing else.

This is one reason, apparently, why rheumatismus neonatorum is not frequently recognized. Another and more potent reason for its non-recognition is the following one: Rheumatism, in infancy and childhood, does not exhibit those marked and characteristic joint affections we are wont to see in adult life. The medical mind is so accustomed to associate rheumatic affections with heat, pain, redness, and swelling of one or more articular joints, that sometimes only through

sheer good luck does one escape the brutal mistake of diagnosing a housemaid's knee as mono-articular rheumatism. Few, indeed, take the trouble to examine the heart of a restless, crying, painful infant, a procedure which may in a moment reveal the cause of the little one's anguish. Rather than this, the dumb creature is dosed with the staple remedies for colic—as, for example, castor oil, brandy, calomel, paregoric, and other things which will occur to the doctor and experienced aunts. Says Dr. James Finlayson, in his excellent article entitled "Diagnosis:"⁵ "Rheumatism in childhood is at times rather difficult of recognition, as the articular affection is only slight, and perhaps contemptuously spoken of as 'growing pains,' although such trivial attacks are often associated with endocarditis, leading to permanent mischief of the heart."

All authorities agree that rheumatism in early life is characterized in a majority of cases by valvular lesions of the heart: or, to put it differently, the heart, instead of the joints, is the target of the disease. In rheumatic fever of that age, a fatal endocarditis is not incompatible with a total absence of articular affection. Endocarditis, in the life of an infant or child, is almost positive proof (sixty per cent. to seventy-five per cent.) of either past or present existence of rheumatism. The inferences to be drawn from this statement of facts are, first, the importance of the routine examination of an infant's heart; and second, the rheumatic origin of an infantile endocarditis.

The lay more than the medical press bristles with reports of sudden deaths of infants. Is it not logical to assume, from what has been said, that this unexpected termination of young lives is as much the result of heart failure as it is in similar cases of older members of the community? And, furthermore, is it not reasonable to ascribe the cause of this form of infantile mortality primarily to acute rheumatism? And yet the abrupt ending of an apparently healthy infant is most often attributed to "convulsions," rather than to its true and probably only cause, rheumatism.

Sir Dyce Duckworth⁶ lately estimated the percentage of chorea as an expression of rheumatism to be about seventy-five. Now, sometimes in the course of our daily practice we come across a case of chorea in a child in whom there is no trace of rheumatism, past or present, in the joints, heart, or elsewhere; and, being at a loss to account for its presence, we are obliged to fall back on the ubiquitous but none the less perfunctory cause, fright. If, however, we kept in our minds the possibility of the child's having had rheumatism in its infancy, which, fortunately, left no indelible trace on it except the chorea, we would not adopt wildcat theories to account for the manifestation of the latter in advanced childhood. Furthermore, if the rheumatismus neonatorum had been recognized, so that the proper remedies could be applied, there would, perhaps, be no chorea to treat later on.

I must now turn to another phase of the subject of this paper—from the practical to what may be called the scientific side.

By recognizing and establishing the existence of rheumatismus neonatorum, we shall add tremendous weight to the modern conception of the etiology of acute articular rheumatism.

Acute rheumatism is struggling hard for recognition as an infectious disease. Some authors of eminence have already recognized its claim, and accordingly admitted it to the republic of infectious diseases; while others acceded it the right of belligerency only, waiting, meantime, for further proof of its deservedness. It is undoubtedly owing to the absence of clinical data, the sheet anchor and touchstone of certainty, that the profession hesitates to adopt that view of the etiology.

* Read before the New York Eastern Medical Society, September 11, 1896.

The rise and fall of the different theories regarding the causation of acute rheumatism are interesting. While all observers agreed upon several factors, such as chill, fatigue, climatic changes, and, last but not least, that mysterious entity—diathesis, as necessary elements in the etiology of rheumatism, yet they could not escape the conviction that something more than all this is at the bottom of the rheumatic constitutional disturbance and its train of disagreeable sequelæ. Here, then, speculation became rife. As a consequence, we have the neuropathic theory, the uric-acid theory, the lactic-acid theory, and the compromising theory, namely, that which promulgates the view that the disease is caused by an excess formation in the blood of uric and lactic acids. There are three more theories: one holds arterio-sclerosis responsible for some cases of rheumatism; another says that it is in a great many instances the fault of the white corpuscles of the blood; and still another attempts to lay the blame at the door of the lymph and its circulation in the lymph spaces and vessels. Dr. Cheadle,⁶ in an interesting review of the entire subject of rheumatism, thus speaks of the chemical theories: "While they command respect and admiration by the knowledge and ingenuity with which they are worked out, they must be accepted only as provisional explanations of the chemical and physiological process by which the result might be brought about, if uric acid should prove to be the ultimate factor of the disease."

These theories being problematical and insufficient, in order to satisfy the mind it was natural for the ingenuity of man to invent a new theory. So we find the theory of infection occupying the arena of speculation. According to Strümpell, this view was first advanced by Huter. The final appearance or evolution of the theory of infection was neither unnatural nor unexpected. It is a step in the direction of modern thought and ideas. If you take into consideration the clinical picture of acute rheumatism, you must be irresistibly impressed with the family resemblance it bears to other infectious diseases. The variety of type, the involvement of the heart, pericardium, pleura, tonsils, joints, and skin; the occurrence of albuminuria, the hyperpyrexia, the liability to relapses; and, lastly, its prompt yielding to a specific remedy—all add shape and color to the family likeness. Of course, this picture is only suggestive, not conclusive. For the theory of infection to become an accepted and indisputable fact, it must conform to three rules: First, it must prove that the disease depends upon a specific micro-organism. The specific germ must be invariably found associated with the disease, it must admit of isolation, and must be capable of reproducing the affection when inoculated in a human being or in a lower animal. A good many investigators set to work to discover the specific microbe. Many were the attempts and many were the failures. The serum of the pleura and joints, the urine and blood of rheumatic patients, and portions of brain and endocardium of patients who died of rheumatic fever were carefully examined, with greater or less encouragement and success. Among the many who were engaged in that work can be prominently mentioned Birch-Hirschfeld, Bouchard and Charriën, Triboullat, Soaza,⁷ and Leyden. While "all repeatedly found the staphylococcus albus and sometimes the streptococci in the synovial and pericardial fluids and the cardiac valves in cases of acute and subacute articular rheumatism," it remained for Leyden⁸ "to isolate from a number of cases of acute rheumatism, attended by complications, a delicate diplococcus, differing from any hitherto described, and unequivocally distinguishable from the various forms of staphylococcus, the streptococcus, and diplococcus of pneumonia." The logical conclusion therefrom is that this organism is the essential cause

of the malady and its complications. If the work of this illustrious man be continued by himself or his followers, we may reasonably expect to hear, sooner or later, of rheumatism being produced in lower animals by inoculating them with the specific diplococcus.

Great impetus was lately given to the second of the three rules by the careful and painstaking researches of Dr. Newsholmes,⁹ of London, viz., the epidemicity of acute rheumatism, or, as he prefers to designate the disease, rheumatic fever. To quote the doctor's words: "All the hospital records, all the Scandinavian imperial returns of cases, and all the death returns agree in manifesting very great irregularities in the yearly incidents of rheumatic fever, the excesses of prevalence in certain years being so great as to merit the name of epidemic." On another occasion he added the following suggestive remarks:¹⁰ "The clinical and pathological features of rheumatic fever were both best explicable on the supposition that it was caused by the entry into the system of a specific micro-organism." He further says: "Low subsoil water and high earth temperature were two of the most important conditions under which the specific micro-organism of rheumatic fever germinated in the soil and became capable of parasitic life in the human body."

Now we come to the consideration of the last and, from a practical standpoint, most important rule or element necessary in the support of the theory of infection.

In the days of yore, clinical data were everything. Nowadays, they stand in humble relation to the omnipotent instrument, the microscope.

As rheumatism is not an eminently infectious disease, evidence of transmission of it is comparatively scant. The same, however, may be said of pneumonia. There are cases on record which apparently show the transmission of the disease from individual to individual, in the same house where rheumatic fever prevailed. But a doubt is thrown on the illustrative accuracy of such records by the probability that all the victims in the same house might have been a prey to the same pernicious climatic or other external influence. I expect that the fetus and the infant will furnish the medical world with all the necessary corroborative testimony justifying the classification of acute rheumatism among the infectious diseases.

Pathologists are at present engaged in a work which, though as yet barren of results, is full of rich promises for the future. I refer to the study of the diseases of fetal life. There are already on record many cases of endocarditis of a pre-natal origin. An editorial writer in the *New York Medical Record*¹¹ thus hopefully sums up the literature of this new and interesting subject: "That a pregnant woman, suffering from an infectious disease, may give birth, prematurely or at term, to a child suffering from the same disease, has been recognized for a long time; and recent experience demonstrates that the transmission takes place through the placenta. We have also learned that any infectious process is capable of causing endocarditis. It may thus happen that the pregnant woman is attacked with rheumatism, or typhoid fever, or influenza, or pneumonia, or other infection, while her unborn infant, though possibly escaping the primary disease, is the victim of an inflammation of the endocardium of the right side of the heart, the consequences of which persist through life." Place these inferential remarks side by side with the accepted origin of the great majority of endocardial lesions in infants and children, and they will be but a splendid commentary on it. But, even putting this new light aside, let us ask the question: Can it be proven that a pregnant rheumatic woman can give birth to a child with acute rheumatism? I believe she can, and that she does. If we keep

our eyes wide open, if we remember that infants and children can have rheumatism without articular troubles, if we make it our business to examine a suffering infant's heart, we shall find in more than one case unmistakable signs of rheumatic endocarditis. Better and more convincing clinical demonstration of the infectiousness of rheumatic fever than that which could be furnished by the infant and its mother, could not be desired. I am, as you know, a general practitioner, and as yet free from the marks of the footprints of time; still, ever since my attention was accidentally called to this condition, I have gathered material and I present to your intelligent and critical examination three undoubted cases of rheumatism neonatorum, which, to all appearances, originated *in utero* of the respective rheumatic mothers—that is to say, women who suffered from acute articular rheumatism either shortly before or at delivery of their children. I shall add to my three cases the histories of the three others I found recorded, and with them all I will beg to complete my paper:

CASE I.—S—, infant, twelve days old; referred to me by Dr. Rosenblueth in the fall of 1891. The baby was perfectly developed, was carried to full term, and naturally delivered. According to its mother, the child did not stop crying from the moment it was born. On being handled, its cries were most pitiful and loudest. At the second bathing, about twelve hours after delivery, the midwife noticed that the child was a little feverish and seemed to be pained when its lower limbs were touched. On closer inspection she found the joints of both knees and ankles, one wrist and one elbow-joint, slightly red and somewhat enlarged, but intensely tender. The left knee was larger and redder than any other of the joints. Thinking that the trouble was a "cold," she applied to both knee-joints "potato poultices," and to the others flannel and wadding. The child seemed to feel better under this treatment, for it nursed and slept quite well. On the fifth day the infant was decidedly feverish, the knees being considerably inflamed. With this change of symptoms the treatment underwent some modification, for now the midwife applied hot linseed poultices. The latter treatment was kept up for four days; the child got worse, and then Dr. Rosenblueth was called in. When he saw the child the left knee-joint was inflamed and suppuration was threatened. A day or two after I assumed, through the kindness of the doctor, full charge of the case.

My examination revealed the following points: Fair-sized baby, crying, restless, and very tender to the touch. Skin moist and acid in reaction. Here and there on the body small erythematous blushes were noticeable, which disappeared on pressure, and were probably the result of irritation caused by the rough flannel in which the child was wrapped. Bowels costive, mouth aphthous; head and fontanelles normal in shape and size. Bones in the body presented nothing unusual. The temperature was 103.5° F. Pulse was so rapid that I could not count it with certainty. The heart's action was tumultuous and irregular. Respiration, from 50 to 60 to the minute. Excepting the shoulder-joints, all the rest were very tender when quiet, and especially so when moved. The left knee-joint, which was diligently poulticed with lard and linseed, was cedematous and purulent. This joint was incised and a thin pus escaped. A few days later the second knee-joint showed signs of suppuration, while the rest of the joints remained in the former condition. The child failed pretty rapidly and died on the eighth day after I took charge of it. The diagnosis of purulent rheumatic arthritis, complicated by acute endocarditis, was arrived at after mature consideration and exclusion of every other possible disease, as syphilis, tuberculosis, rachitis, erysipelas, or pyæmia. The

parents were absolutely free from all infectious, contagious, or communicable diseases, past or present, save one, and that was rheumatism. The cord was healthy, and no other avenue for entrance of sepsis to cause pyæmia could be discovered. I must add that the diagnosis of purulent rheumatic arthritis was made after the death of the infant, when in my leisure I could go over the entire history of the case with extreme care and minuteness. Mrs. B—, the infant's mother, suffered from an attack of acute rheumatism two weeks before delivery, and, while her acute symptoms were gone at delivery, she still had pain in some of her joints. Mr. B— was a victim of a mild chronic rheumatism and experienced frequent exacerbations. There may be humor and truth in his wife's remark that he had an equal share in the infant's death, for at the time of conception he suffered an exacerbation.

CASE II.—Mrs. M—, twenty-eight years old; family and personal history negative; pregnant for the third time. When she entered her ninth month of gestation, she was attacked by acute articular rheumatism. On the fourteenth day of her sickness I was called in to see her. I found her lying in the recumbent position, unable to make the slightest movement. I was informed by her relatives that she had been on her back ever since she was taken sick. All the joints, small and large, were involved. Both hip-joints were very tender, but there were no visible signs of inflammation. On forcibly turning her on one side, I discovered in the lumbar region an immense bed-sore undergoing sloughing and ulceration in several places. The temperature never ran lower than 104° F. morning and evening. The heart was rapid, but no damaged valve could be discovered. The pericardium and pleura were normal. In spite of large doses of salicylate of sodium, there was no diminution in the severity of symptoms and no reduction in the temperature. The bed-sore, owing to difficulty in turning her, could not be treated as well as was desired, and therefore it made very little progress in the direction of healing. At the end of the twenty-first day of her illness the temperature began to rise, and in less than twenty-four hours it reached 106° F. At this period I could detect for the first time an aortic murmur. Her pregnancy all the while went on undisturbed. The fœtus showed unmistakable signs of life by violent kicks, which added much to the poor woman's agony. On the twenty-fourth day of the disease the temperature went up, at times as high as 107° to 108° F. The condition of the heart became alarming: the aortic insufficiency was very much pronounced, the heart action was frequently irregular and tumultuous, and the patient at times was quite delirious. The urine showed no lesion of the kidneys. At this stage I decided to induce premature labor to save the child and possibly relieve the mother; but before doing so I consulted Prof. Paul F. Mundé. The professor saw her in the evening of the twenty-fifth day of her sickness. He regarded the case as very serious, but detecting feeble uterine contractions and finding the os somewhat dilated, advised against the induction of labor, predicting that she might be delivered in twelve hours. She was delivered the next evening of a boy weighing about nine pounds, well developed in every respect. Shortly after delivery the symptoms abated, but not for any great length of time. Three days after delivery the temperature rose again; the heart action was very rapid and very feeble. She was removed in this condition to Bellevue Hospital, where she died with a temperature of 109° F. The autopsy showed, in addition to other and minor things, an acute endocarditis involving the aortic and mitral valves; very little fluid in the serous cavities; serum of some of the joints was purulent; the uterus was perfectly normal.

In bathing the infant two hours after it was born, I noticed that it was not quite as supple as other infants are. I also noticed that its legs were somewhat drawn up, and when they were straightened it protested in unmistakable tones. Examining carefully, I discovered tender, somewhat stiff, but not swollen knee-joints. It seemed that the calves of the legs, as well as the muscles of the arms, were sensitive to the touch. Examining the heart, I found a distinct, soft, blowing, mitral systolic murmur. The temperature was 101.5° F. The highest point the temperature reached was on the fifth day, when it went up to 103.5° F. In that condition the heart was so irregular and the pulse so small and rapid that it was superfluous to count it. On the sixth day the temperature went down again to 101° F., and the heart action improved. There was considerable difficulty in keeping the infant in a good condition. The food was artificial, the feeder was careless, and all the surroundings were pretty bad. In spite of all these disadvantages, the child got along fairly well, and under the careful and judicious use of salicylate of sodium (two to six grains per day) the little patient completely recovered within six weeks of his birth. The joints were supple and free from pain, and the heart ceased to show any abnormal sign; in other words, the baby was cured. It kept up in excellent health until the age of six months, when it developed acute gastro-enteritis and died.

CASE III.—Mrs. K——, primipara, aged twenty-five. Rheumatism in the family; mother and father had it. In the beginning of the seventh month of her pregnancy she was attacked with subacute articular rheumatism; different joints became stiff and painful from time to time; her temperature was never higher than 100° to 100.5° F. Her heart was normal. Under the use of salicylate of sodium (sixty grains per day), she recovered in ten days. She felt well up to the middle of the ninth month of gestation, when she was seized with quite a violent attack of chorea; the choreic movements were bilateral. Within twenty-four hours of the attack labor began, and terminated in forceps delivery under chloroform anæsthesia. It may be interesting to note that the chorea stopped the minute the placenta was expelled. The infant, which was a female, was apparently healthy, nursed, and slept well. It could twist and turn its limbs whichever way it pleased with safety. No tenderness was ever elicited. But one thing was noticed, viz., when it cried the face and finger tips became abnormally blue. This condition suggested endocardial trouble, and accordingly I examined the heart, with the result of finding an aortic insufficiency. No elaborate explanation was necessary to account for the origin and presence of endocarditis. The result of treatment in this case with salicylates is not satisfactory.

The following cases are those which were referred to in the beginning of the paper, and in which the diagnosis of acute rheumatism was made:

CASE IV. (Strümpell's case).—He refers to it in this wise: "We may be permitted to mention a single interesting case which we met in Leipsic, where a child who died when only a few days old, and whose mother at the time of its birth was suffering from a severe attack of acute articular rheumatism, was found to have multiple purulent arthritis."

CASE V. (Pocock).—The reporter calls this "A Case of Acute Rheumatism, Occurring in a Newly Born Infant, treated with Salicylate of Sodium." On May 25th the doctor was called to see a Mrs. A——, whom he found suffering from acute rheumatism, with a temperature of 106.5° F. She "was pregnant within a month of her confinement." Thirty-six hours after she was seen labor set in. Delivery was accomplished in four hours. "The child was a very cross one and

cried very much, which the nurse and mother attributed to flatulence and want of food. However, dill-water, aniseed, etc., having no effect, I was sent for about twelve hours after birth. The child was decidedly feverish, with a moist skin, and an acid smell about him. I noticed that he appeared to cry more loudly whenever his right arm was moved. On removing the dress his right shoulder and elbow joints were found reddened; and on moving either joint he cried lustily. On using the thermometer I found the temperature 103.5° F., and his pulse 170, as accurately as I could count it. Under the circumstances, it occurred to me that he might have the rheumatic poison in his blood, and that, in fact, I had to do with a case of congenital rheumatic fever." The diagnosis was corroborated by the influence the salicylate had on the patient, for the child was completely cured.

CASE VI. (Schäffer).—The reporter of this case calls it a "Case of Acute Articular Rheumatism of the Mother and her Newly Born Child." A woman, aged thirty-five years, in her fifth pregnancy, suffered from an attack of acute rheumatism a few days before delivery. At full term a thoroughly healthy child was born. The child was rapidly delivered. "The midwife noticed on the third day a slight swelling on the back of both feet; the temperature was 38.7° C.; appetite poor. On the following day the swelling of the feet increased. The phalangeal joints of the first finger of the left hand began to show signs of redness and swelling. A doughy swelling was found in the neighborhood of the left hip-joint. There was no recognizable change in the heart. A day later the redness spread over both hands and all the finger-joints and both hip-joints. Temperature, 39.5° C. The child lies now more motionless, tightly-drawn hips; the arms, when slightly moved, make the child cry pitifully."

The writer of this report was sanguine in his convictions that this was a case of acute articular rheumatism in the newly born, acquired in the intra-uterine life.

Now, gentlemen, if I have succeeded in convincing you of the existence of the disease which I ventured to christen *rheumatismus neonatorum*, my work will be sufficiently recompensed; but if I also succeeded in rousing your interest in this unrecognized disease, so that in time you may help, through your intelligent observations, to increase its literature, I shall consider myself doubly and trebly rewarded.

Dieting in Dyspepsia.—Dr. Balfour, in his work on "The Senile Heart," gives the following rules for dieting which are applicable in many cases of dyspepsia: (1) There must never be less than five hours between each meal. (2) No solid food is ever to be taken between meals. (3) All those with weak hearts should have their principal meal in the middle of the day. (4) All those with weak hearts should have their meals as dry as possible.

SENILE ENDOMETRITIS AND VAGINITIS.¹

By AUGUSTIN H. GOELET, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC.

THE assumption that women are necessarily exempt from uterine disease after they have passed the menopause is an error. It is a mistake also to think that they are peculiarly exempt from inflammation of the genital tract, though it may be true that they are not so liable to acute inflammatory conditions as younger women, or rather when inflammation occurs at this age it is not apt to be so active. This belief concerning women past the climacteric is prevalent with the laity and is strengthened by the attitude of the profession at large, who are prone to regard the question with indifference. This may be due to the belief that there is little to be done for chronic inflammation of the uterus if it exists at this time and that it is incurable, hence it had better be left undisturbed. This is an error which is the result of past ineffective methods in dealing with inflammation of the uterine mucosa in general and of the attempt perhaps to apply here the same method of treatment that is effective in other forms of endometritis depending upon quite a different cause and presenting quite a different pathological condition.

If the general practitioner will come to realize that women past the menopause may be liable to a chronic inflammation² of the uterine mucosa and that it is amenable to treatment, he will begin to look for signs and symptoms denoting it and he will find that it is by no means infrequent. He must be prepared for opposition on the part of the patient, who at this age is always reluctant to admit the possibility of such a condition and who would endure anything rather than submit to treatment for it. He will find it difficult to convince her that, having enjoyed, as she believes, an immunity from womb trouble previously, she can possibly have any such disease after the menopause. Yet, strange as it may appear, senile endometritis is more frequently found in women who have not received treatment for uterine disease earlier in life. This may be explained on the assumption that catarrhal inflammations, if they existed previously, were neglected because of the reluctance of most women to submit to treatment unless forced to do so on account of the severity of the symptoms. Still this does not by any means account for all of the cases of senile endometritis, for it has been discovered not infrequently in women who from the closest scrutiny of their histories gave no evidence of any uterine disease whatever during their menstrual life, and I have seen it in women who had never married and never had children, and who had remained virgins. Hence I believe that, while senile endometritis may result from neglected endometritis occurring during menstrual life, the change in the uterus incident to the menopause is directly responsible for a great number of cases.

There can be no doubt that an impaired condition of the general system may be a strong factor in the production of senile endometritis which should not be overlooked. Yet by far its most active cause is the atrophic changes which the uterus undergoes at this time of life, depending upon a diminished activity of the pelvic circulation resulting in impaired nutrition of the organ. Not only does this alter the character of the glandular structure and of the secretions, but the epithelium of the mucous membrane undergoes a radical change and in some instances disappears com-

pletely. A general shrinkage and contraction occur and the canal of the cervix becomes narrower in calibre and eventually becomes obstructed, sometimes even almost obliterated. This condition is hastened by destruction of the mucous membrane in places, due to the acrid character of the discharge, resulting in the formation of bands of cicatricial tissue. These changes are not limited to the mucous membrane of the canal of the cervix, but involve the whole endometrium and are also to be observed in the vagina, where not infrequently, if the disease has been neglected, the vaginal vault is so narrowed from contraction of cicatricial bands that it is difficult to reach the cervix in some cases. I have been able to show at my clinic repeatedly cases of this kind and also to demonstrate the cicatricial contraction of the cervical canal.

The appearance of the mucous membrane of the vagina is characteristic in these cases. The rugæ are effaced and the surface is pale and glistening in places, a more nearly normal membrane intervening, upon which may be observed minute ecchymosed spots or apparently elevated intensely reddened papillæ, which consist of exposed capillary vessels, the epithelium being destroyed, they show through the delicate structure covering them. In some cases the whole surface of the vagina is intensely injected and inflamed, and is covered with an acrid muco-purulent discharge, derived in great part from the uterus. An active vulvitis is sometimes produced by contact of this discharge.

The uterus is the seat of change beyond that of the mucosa. Its walls are in some cases atrophied and the organ is much reduced in size. In other cases the walls are softened and the organ is enlarged and relaxed, which may be due to constant distention from the secretion retained within the cavity.

The character of the discharge is muco-purulent or sero-purulent, depending upon the duration of the disease and the extent of the changes that have occurred. It is usually more profuse and acrid as the disease advances and if it has been neglected. It is profuse at times, then again almost absent, because it is often retained from obstruction of the canal until over-distention causes its expulsion. The discharge is sometimes, though rarely, mixed with blood.

The symptoms which this condition gives rise to are by no means constant or invariable. Sometimes the patient will complain of a burning on the top of the head or a burning pain in the lumbar region or over the sacrum, but seldom is pelvic pain a prominent symptom. Pain is more often complained of when a posterior displacement of the uterus complicates the case. I have known these patients to suffer positive discomfort while riding in a carriage even over a smooth road.

Rectal tenesmus, due to a chronic proctitis, is sometimes complained of. Vesical tenesmus is more frequent, and in some instances there is a chronic cystitis with urethritis and a discharge from the urethra, muco-purulent in character.

The digestion is often impaired and with it there is marked evidence of malnutrition, giving a worn expression and the appearance of premature old age (Skene). This is perhaps due as much to chronic sepsis as to reflex disturbances caused by the local irritation. The appearance is so characteristic that patients suffering with senile endometritis may often be told by their general appearance, the facial expression, and the peculiar bronzed appearance of the skin. The general circulation is poor and these patients suffer with cold extremities, a dry irritable condition of the skin, great nervousness, and not infrequently insomnia.

If a patient past the menopause complains of disordered digestion, is thin and poorly nourished, the

¹ Read before the New York Medico-Surgical Society, October 5, 1896.

² Skene is inclined to regard this condition as a senile degeneration in the majority of cases rather than as a chronic inflammation, with which view the author concurs.

skin is dry and irritable, and the general circulation is poor, a diagnosis of senile endometritis is safe, even if she denies the existence of any discharge or pelvic symptoms, and I always insist upon an examination, especially if her symptoms have resisted treatment for their relief.

Treatment.—To apply here the same method of treatment that is employed for endometritis in younger women will meet with signal failure. The attempt to dilate the obstructed canal with the steel dilator or graduated bougies in the usual manner will in many cases result in rupture. When the disease has progressed to the stage in which cicatricial bands have formed, rupture is certain to occur if forcible dilatation is attempted. These bands will not yield, consequently the intervening soft, friable tissue gives way. The use of the curette in most cases is unwise and unnecessary. The mucous membrane has already been destroyed and nothing remains to be removed. Likewise the application of caustics and irritants to the endometrium is most injudicious. Enough injury has already been done by the acrid secretion and only harm can result from such harsh measures.

Dilatation of the canal to promote free drainage of retained secretions is most important, in fact absolutely imperative, for persistent drainage with absolute asepsis of the endometrium is the only manner of effecting a cure. How drainage is best accomplished and how maintained, is the main question at issue.

In the early stage, when only a year or two have elapsed since the menopause, and particularly if there is retroflexion of the uterus, dilatation to rectify the malposition and careful curettage, followed by appropriate after-treatment, are unquestionably the wisest measures to adopt, but later these are not only useless but unwise. At this stage dilatation if carefully done will produce no injury, and the curette may be used to advantage, but after-treatment to maintain a patulous condition of the canal and an aseptic condition of the cavity by repeated irrigation must be persistently carried out.

In the beginning the patient's confidence must be gained, and she must be made to appreciate the fact that her disease is essentially chronic and dependent upon the natural changes that the uterus must undergo at this period; that these changes are progressive and continuous up to a certain point, and that consequently a cure cannot be accomplished quickly. She must therefore be made to realize the importance of keeping herself under observation and under treatment at gradually increasing intervals until these changes are completed. This done, we are prepared to undertake the treatment of the case and can promise not only speedy relief of her symptoms but a positive cure, if it has not been too long neglected and malignant degeneration has not occurred.

In those cases in which the disease has progressed and forcible dilatation is not permissible, some other means must be adopted for freeing the canal and maintaining drainage. For a number of years I have employed with entire satisfaction in these cases the negative pole of the galvanic current through conical electrodes of gradually increasing size. This will inflict no injury if care is taken to avoid cauterization or destruction of tissue by using a moderate strength of current. When the necessary degree of dilatation is accomplished in this manner, a small clinical double-current irrigator is inserted, and the cavity is thoroughly irrigated with a weak solution of lysol (one-half to one per cent.). The irrigator has an attachment which permits it to be utilized as an electrode, and it is connected with the negative pole of the battery and the current (ten to fifteen milliamperes) turned on while the irrigation is going on, from a half to one pint of the solution being used each time. Thus,

through the medium of the water, the stimulating effect of the agent is obtained upon the whole endometrium, and the cavity can be most effectually cleansed. The reaction of the current seems to enhance the value of the lysol solution in removing the sometimes tenacious secretion which adheres to the surface of the endometrium and is not otherwise easily removed. It seems likewise to neutralize the virulence of the discharge, which has an acid reaction.

After one or two applications the canal will usually remain sufficiently patulous to permit the introduction of the small irrigator without using the dilating electrodes previously, if too long an interval has not intervened. The irrigation should be repeated every two or three days during the first week or two, and as the condition improves the interval should be lengthened. Thus, during the second month once a week will suffice in some cases and during the third month once in two weeks. Then the patient should be required to return for treatment once a month for a few months. Some cases will improve more rapidly and others will require even a longer time before a positive cure is effected.

The surface of the vagina must be cleansed also, either by means of the irrigator with the lysol solution or it is wiped out with a pledget of absorbent cotton wet with the same solution and held in the grasp of a dressing-forceps. The vaginal surface and vulva as well are then dusted freely with some bland non-irritating antiseptic powder. For this purpose I have employed with much satisfaction markasol, a new preparation, said to be borophenate of bismuth, which answers the purpose admirably in counteracting the virulence of the discharge and soothing the inflamed membrane.

The patient is directed also to use the same powder in a vaginal douche once or twice a day, dissolving a teaspoonful in a quart of warm water. If the vulva is inflamed or excoriated, the surface after it has been thoroughly washed with the solution and dried is kept dusted freely with this powder. The labia are kept separated with a layer of absorbent cotton, which is removed when it becomes moist.

If the uterus is retroflexed it must be rectified, and, when possible, a vaginal pessary inserted. In those cases particularly not long past the menopause, the displacement can best be overcome by first carefully dilating and straightening the canal in the manner I have described elsewhere for overcoming retrodeviations. In some cases, however, the shrinkage and contraction of the vaginal wall will make impossible the employment of a pessary to any advantage. In these cases ventral suspension of the uterus may be resorted to. I cannot think that a hysterectomy would be justifiable for this condition, since I have never yet met a case that did not yield to the plan of treatment here outlined.

When the bladder is involved, it must receive attention also. It should be washed out twice or three times a week in the beginning with a saturated solution of boric acid, or, what I very much prefer, markasol, half a teaspoonful to a quart of warm water, because it is more soothing and the relief which it affords is more permanent. For this purpose the double-current irrigator or a glass catheter may be employed. It will usually be found that the urethral mucous membrane has undergone a decided change and has lost its epithelium in places, as shown by the intensely injected folds which project at the meatus, resembling very much urethral caruncle. At the entrance to the bladder the membrane is hypertrophied and very hyperæsthetic, and complete evacuation is prevented. This retained urine becomes decomposed and provokes irritation. For this condition I have found that dilatation of the urethral canal with the

conical dilating-electrodes connected with the negative pole yields the best result. Only a moderate strength of current (five milliamperes) should be used for two or three minutes each time the bladder is washed out. The vesical tenesmus and inflammation are promptly relieved by this method of treatment, and the patient will feel well repaid for the inconvenience it causes at the time.

In some instances the treatment of these cases of senile endometritis and its complications is tedious and taxes the patience of both physician and patient. But if in the beginning she is made to understand the situation clearly and can be made to appreciate the fact that improvement and relief of symptoms do not mean a cure, she can be controlled and kept under observation until a positive cure is effected, and she will be amply repaid by the relief it affords. I know of no gynecological disorder the treatment of which I undertake with more certainty of success.

108 WEST SEVENTY-THIRD STREET.

CHRONIC ENDOMETRITIS.¹

By JOSEPH BRETTEAUER, M.D.,

ASSISTANT GYNECOLOGIST, MOUNT SINAI HOSPITAL; ASSISTANT SURGEON, NEW YORK CANCER HOSPITAL.

I OUGHT to apologize for bringing before you a subject apparently so trite and so often discussed. It is, however, my firm belief that there are no, or at least not many, pathological conditions which we meet so frequently, explain, and consequently treat so differently, as chronic endometritis. It is this circumstance which induces me to read this short paper, which is not meant to solve scientific questions, but simply to deal with clinical facts.

It has been, and with some observers is still, customary to distinguish between cervical and corporeal endometritis. Although there is normally a vast difference in the structure of the cervical and corporeal epithelial linings, there is very little when they become chronically inflamed; in other words, the process and results of chronic inflammation are the same in both parts of the uterus. Furthermore, it is extremely difficult in most cases to decide to which part the disease is limited, if such a thing as limitation in a chronic state of inflammation actually exists. For these reasons I shall embrace the whole subject as endometritis, instead of differentiating endometritis corporis and endocervicitis.

For practical and clinical purposes, I still adhere to the distinction of simple or catarrhal and infectious or purulent endometritis; although I quite agree with a lately advanced opinion, according to which endometritis is always caused by bacteria.

The etiology of catarrhal endometritis may be varied in its factors, but it must be distinctly understood that there can be no actual endometritis unless pathogenic bacteria have entered tissues whose resistance to their invasion has been lowered. Normally, we find the gates open for the entrance of bacteria to the endometrium; but, unless the vitality of this mucous membrane has been impaired by disturbances of circulation, their presence is harmless. These circulatory disturbances consist either in active hyperæmia, as, for instance, in a fibromatous uterus; or in passive congestion, as in displacements, stenosis of the cervical canal, habitual constipation, and in numerous vascular and neurotic conditions. The results of these vascular disturbances are œdema and hypertrophy, both of which are increased in proportion to the permanence of their existence, and furnish an excellent culture medium for the producers of the inflammatory process.

¹ Read before the Metropolitan Medical Society, May 26, 1896.

In instances of purulent endometritis, however, we are not obliged to seek such a complicated etiology; for we can usually trace the condition directly to a previous acute infectious process. This may have been general, as an accompaniment of any acute infectious disease (scarlatina, cholera, diphtheria, etc.); or it may have been local. The local infection may have been gonorrhœic or septic; the latter subsequent to abortion, puerperium, or instrumental manipulation.

As a matter of interest only, I will add that lately, in some cases of endometritis, protozoa (*amœbæ*) have been found, and were supposed to be the cause of the disease.

Pathologically, we can distinguish two kinds of endometritis, one of which affects mainly the glandular structure of the endometrium, the other its interstitial tissue. In the glandular form of endometritis we have, first, an increase in the epithelial cells, a growth and a dilatation of the glands—an hypertrophy. If the process continues, an actual hyperplasia of the glandular elements follows, very often at the expense of the interstitial tissue. This hyperplasia may occupy only a part of the endometrium and form polypoid growths, or it may involve the entire cavity, the so-called fungous endometritis. If the interstitial connective tissue is the main seat of the morbid process, there is primarily a round-cell infiltration of a greater or less degree, depending upon the participation of the cellular elements alone or the intercellular substance as well. We always find connective-tissue proliferation in inflammatory processes of long duration, and this may lead to an increase in the size of the uterus as well as to a rarefaction of the glandular structure of the endometrium. I may add here that in cases of so-called senile endometritis, which appear during and after the menopause, in which there is often a total disappearance of the glandular apparatus, it is more than likely that the process does not rest on an inflammatory basis, but more probably upon a purely physiological atrophy or upon a general disease of the blood-vessels.

We find, of course, that the two distinct forms of endometritis may be blended, or that a mixed form may appear, in which all the histological elements of the uterus are involved, although not necessarily in equal measure. In these cases we have the endometritis combined with metritis, a condition which to my mind is more often the rule than the exception.

Although, commonly, a chronic endometritis seems to be free from serious results, it may and frequently does evoke symptoms, after a duration of some time, which would point to a much more serious disease than actually exists.

As in all chronic conditions, we find the symptoms of chronic endometritis to be local and general. Among the local symptoms one of the most prominent is an increased secretion, muco-purulent or purulent, often with a secondary effect, pruritus of the vulva. Menorrhagia, metrorrhagia, and dysmenorrhœa, all in greatly varying degrees of intensity, are the symptoms which most often cause the patient to seek medical advice. Sterility or frequent miscarriages are found to be due to chronic endometritis. Bimanual examination often discloses an enlarged, flabby uterus; the introduction of the sound is more painful than usual, and is easily followed by slight bleeding.

Erosions of the vaginal portion and hypertrophy of the cervix are symptoms which are almost pathognomonic of a very long existence of the disease. Among the group of local symptoms, we must include the expulsion of parts of the endometrium or of the endometrium in its entirety, as it occurs periodically in that peculiar form of endometritis which we call membranous dysmenorrhœa. In this variety, by the way, an interstitial inflammatory process unquestionably exists,

as described in other forms, with this difference, that the process is influenced by the menstrual wave and is localized between the endometrium and the submucous tissue. An intense exudation into both of these layers is followed by a necrosis and shedding of the more superficial one.

The general symptoms of a chronic endometritis vary widely in individual instances, and it must be noted that they are frequently in their severity entirely out of proportion to the local conditions. Some of these manifestations are the logical and natural outcome of the disease present; others depend on nervous origin—for a sensitive woman, once told that her sexual apparatus or any part of it is not in normal state, is apt, as is well known, to imagine pains and sensations which are far from real. The gastro-intestinal tract furnishes the most pronounced array of symptoms in this group. The most frequent manifestations are indigestion, nausea, vomiting, and flatulence, which may produce or be accompanied by diminished peristalsis. Headaches, more or less persistent, emaciation, and irritability of temper, or physical depression, not infrequently appear in connection with endometritis. These latter symptoms it is permissible to refer to reflex influences, since the intimate connection of the sexual organs and the central nervous system is so well known as merely to require mention. The fact that the gastro-intestinal symptoms above mentioned are, in a more intense degree, typical symptoms of acute septic processes within the pelvis, makes the supposition more than probable that in chronic endometritis these symptoms depend also, to some extent, upon a continuous absorption of toxic elements into the blood.

The treatment of chronic endometritis at the present day retains some relics of a bygone therapeutic age; but the indications and contraindications for every form of treatment must be clearly set forth. I can scarcely emphasize too strongly the *noli tangere* which should apply to cases based on constitutional conditions occurring in virgins and young married women. Believe me, the harm resulting from local treatment in these particular instances far outweighs the benefits derived. The mechanical irritation at the vulva, the pain necessarily produced by treatment, and, above all, the deep psychical effect of such measures upon the patient, are more pronounced in their bad results than the good we might possibly be able to do. Should there be symptoms, however, which clearly indicate interference—as, for instance, prolonged menorrhagia or obstinate metrorrhagia, which do not yield to internal medication—thorough curettage under anesthesia, with the correction of existing retrodisplacements, is the only rational treatment. In other cases of chronic endometritis, the treatment that has been advocated is so varying and so different in its technique, that I am compelled to restrict myself to a few of the most important.

The methodical irrigation of the uterine cavity with antiseptic solutions was believed, a few years ago, to be of great value in the treatment of this disease. But experience has shown that the throwing of bactericidal agents into the uterus produced no beneficial effect upon tissue already diseased. Although in the acute stage of endometritis dilatation and irrigation are followed by excellent results, this method has no hold in chronic cases. Another form of treatment was received with great favor at the time of its promulgation, but is at present considered even inferior to the first. This consists in the dilatation and packing of the cavity with iodoform gauze, to procure drainage. It was found, however, that only serous fluids escaped through the capillary action of the gauze, but solid substances, such as clots of fibrin and necrotic tissue, were retained, and not infre-

quently caused alarming complications. Still, in certain selected cases of endometritis combined with metritis, the tamponing of the uterus may yield beneficial sequelæ, since the gauze, acting as a foreign body, may cause contraction of the organ, an effect very much to be desired.

The electrolytic or galvanic treatment of chronic endometritis was heralded as a panacea for this ailment. It was alleged that finally the treatment for chronic endometritis had been found. But in its results it proved no more satisfactory than methods previously tried and discarded. In cases in which metrorrhagia is stubborn and the process is limited to the superficial glandular tissue, some good effects may occasionally be seen from galvanic currents of from one hundred and fifty to two hundred milliamperes strength. But, in general, it may be safely said that the electric treatment of chronic endometritis may be omitted from our therapeutic resources without loss.

At the present day the most effective treatment of chronic endometritis consists of two elements—rational intra-uterine cauterization with chemical agents, and curettage; and, in some cases, the combination of both measures. The most important agents used are the nitrate of silver, the compound tincture of iodine, the strong mineral acids, and the chloride of zinc. The purpose of this cauterization is to destroy the diseased layers of the endometrium and arouse reactionary inflammation, followed by necrosis and final expulsion of these tissues. The remaining tissues then take on renewed growth, and normal endometrium is usually the ultimate result, or at least the expected result. The destruction of tissue varies, of course, in intensity under the influence of different reagents.

In the use of these therapeutic measures, one must always remember the length of time required for each of the caustics to act, since it is impractical as well as useless to repeat the cauterization until the effect of the previous one has disappeared.

After an application of the tincture of iodine, for instance, it takes from three to four days for the period of expulsion to be reached; whereas, the application of a stronger solution of chloride of zinc—from twenty-five to fifty per cent.—requires two to three weeks to effect a similar change in the endometrium; but the diseased layers are then affected to a much higher degree.

My own experience is that in those cases of chronic endometritis in which there is an increased secretion, be it muco-purulent or purulent, the chloride of zinc is an invaluable therapeutic agent. I am accustomed to use a twenty-five-per-cent. solution applied on an ordinary applicator twice during the menstrual interval—that is, from twelve to fourteen days apart. After a very few applications I have found in the majority of cases a radical change for the better. I believe that the fear, so often expressed, of causing a stenosis of the uterine canal by the use of this agent, is overrated, for I have never seen any such result after its use in the strength and at the intervals mentioned. In no one case do I use this method more than from four to six times; for, if decided improvement is not then manifested, another plan of treatment, usually curettage followed by cauterization, is indicated. After quite an extensive experience with the use of a number of chemical agents in varying strength, I have reached the conclusion that by the use of chloride of zinc in a stronger solution (twenty-five per cent.) I require a smaller number of applications and accomplish better results more quickly.

In cases of chronic endometritis in which hemorrhage is the leading symptom, or in which there are extensive erosions, an hypertrophied cervix, or deep lacerations, it is practically useless to begin a course

of local treatment before curetting the uterus thoroughly and performing the necessary plastic operations. After these operative measures have been carried out, and there are still symptoms which show that a radical cure has not yet been effected, this latter will be attained by a very few applications of the chloride of zinc. It is, I think, a mistake to make an intra-uterine application immediately after curettage, since the endometrium is filled with blood, partly fluid, partly clotted, and the caustic never touches the surface it is supposed to affect.

In conclusion, let me say that since following the principles that I have briefly attempted to elucidate here, I have had the satisfaction of attaining good results, even in that class of cases which formerly resisted all possible measures, and, in fact, seemed incurable.

45 EAST SIXTY-FOURTH STREET.

ERUPTIONS OF THE SKIN PRODUCED BY THE LOCAL APPLICATION OF ICHTHYOL.

By J. C. McGUIRE, M.D.,

DERMATOLOGIST, GARFIELD HOSPITAL; PROFESSOR OF DERMATOLOGY, GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

THOUGH it is acknowledged that many drugs when applied to the integument are capable of producing eruptions in those peculiarly susceptible to their effects, the fact is frequently overlooked or ignored, much to the discredit of the diagnostician and the discomfort of the patient.

We not infrequently find that the very remedies used either locally or internally, for the relief of cutaneous diseases, are really the chief factors in the causation and aggravation of these maladies.

Ichthyol, called by Unna sodium sulpho-ichthyolate, and first recommended to the profession by R. Schrotter, is the distillate of a deposit of petrified fish and marine fossils found in Tyrol and Seefeld.

It has been used extensively as a substitute for sulphur to lessen hyperæmia, to cause desquamation of the epidermis and increased action of the sebaceous glands; though highly recommended by some dermatologists in such diseases as sycosis, acne, psoriasis, and the dry forms of eczema, it has been vigorously condemned by others. Piffard, who was the first to employ it in this country, said he used it as long as he could afford to, but he at last had to stop it or lose his patients. G. T. Jackson says that it is an unreliable preparation and not so good as many old and well-approved remedies; he found that it aggravated some of the diseases in which he applied it locally. Unna, though enthusiastic in regard to its beneficial effects in certain diseases, declares that when it is applied to raw surfaces it will produce catarrhal inflammation with œdema and pain.

I can find only one reference to any unpleasant result from its local application to the sound skin or in cutaneous diseases in which the corium is not exposed.

Dr. Morrow in his treatise on drug eruptions does not refer to it, nor have I seen any reference to it in the magazines or text-books, with the exception of Hyde's "Diseases of the Skin," 1893. He says, quoting Sinclair: "The unpleasant results have been reported as following its application in only a single instance. A four-months-old infant sank in a state of stupor two hours after its head and limbs were smeared with a salve composed of one part of ichthyol to five of vaseline."

Considering the infrequency of any deleterious re-

sults from its local use, the report of the following cases may be of especial interest:

Mrs. C—, referred to me by Dr. Cuthbert, reported that she had a scaly eruption of several weeks' duration on the back of the hands and wrists. Within forty-eight hours it had grown much worse in appearance and had caused much itching. On examination the hand and wrist were found to be swollen and extremely red. I ordered a salve containing fifteen per cent. of ichthyol in lanolin and water to be constantly applied. The next day the parts were more swollen and exuded serum from many ruptured vesicles. The sensation of itching had given place to burning and pain. The rash had extended over the whole hand and most of the forearm. I immediately stopped the ichthyol salve, and substituted lotions and dusting powders. Within twenty-four hours the parts were looking even more angry and inflamed. An acute vesicular eruption had appeared on the face. Here the exudation was so excessive that the features were almost obliterated; the nose and lips were enormously swollen, and the eyelids were completely closed. Dr. Cuthbert then informed me that he too had advised a mild ichthyol salve two days before I had seen the patient. A few hours later the symptoms had grown much worse. Though I was convinced that the ichthyol had caused the trouble, after the rash was looking somewhat better the same salve (with the full knowledge of the patient) was applied to the unaffected hand and wrist, when the same phenomena occurred within three weeks. The first eruption disappeared, however, and even "the rough itchy condition" of which she first complained was entirely relieved. In one year there has been no return of the trouble. She declared that this was the first time she ever had a rash upon the skin.

Mrs. S—, referred to me by Dr. W. W. Johnston. A week previously the physician who was then in attendance had applied an ichthyol ointment to her knee, which she had severely sprained in falling from a bicycle. She had rubbed the salve above and below the knee and over the calf of the leg. When I first saw the patient the skin was intensely inflamed from the middle of the thigh to the ankle, exuding a great quantity of serum that caused her stocking to adhere to the leg. The face was very much swollen; the eyelids were almost closed; there were a few discrete vesicles over the right thigh and leg. The patient was in a highly nervous hysterical condition, crying from the intense pruritus that gave her no rest night or day. She stated that she had never had an eruption of any kind on her body previously to this time, that her skin had been unusually free from all blemish. The eruption had appeared only a few hours after applying the salve, at first simply as a hyperæmia, followed the same night by a vesicular eruption and most intense itching. I applied cooling lotions and dusting powders. There was immediate improvement in the appearance of the eruption, which continued until, two weeks after the first appearance of the rash, there was hardly a sign of it left, but the pruritus still persisted. Carbolic acid and oil of peppermint lotion sprayed on the parts, followed by dusting powder of talc, gave relief, though she still complains of some pruritus. As there are no eruption and no scratch marks, this subjective sensation can be accounted for by the hysterical and nervous condition of the patient, brought about by worry and loss of sleep.

In both of these cases the eruption was probably caused by direct contact of the ichthyol, rather than by absorption through the skin, as the epidermis was unbroken (especially in the case of Mrs. S—) when it was applied to the perfectly sound integument. Though it is usual in all medicinal rashes for the

local manifestations to improve on the withdrawal of the drug, in some cases they continue for quite a little while. A disease of the skin may continue long after the cause has ceased to act, whether the etiological factor is local or constitutional.

818 SEVENTEENTH STREET.

Progress of Medical Science.

Congenital Absence of Kidney.—Ballowitz has gathered all available recorded cases of congenital absence of one kidney. They number two hundred and thirteen, to the exclusion of cases of fused kidney and of partial atrophy of one kidney. Relative to sex, this imperfection occurs nearly twice as often in males as in females, a circumstance attributable in a measure doubtless to the greater frequency of necropsies on the former; relative to age, there were twenty-three in fetuses, most of which had some other malformation, especially imperforate anus; the others were about evenly distributed up to seventy years of age. All cases considered, this deficiency is more often on the left than on the right side, and though the left kidney is more generally lacking in males than the right, in females the defect is equally common to both sides. In form and relation, the solitary kidney was almost invariably normal but much enlarged, apparently owing to hyperplasia rather than to hypertrophy. In many cases there were attendant deformities of the procreative organs, most constant on the side of the renal defect, the conducting channels being modified more than the glandular portions.—*Yale Medical Journal*.

Preventive Treatment of Inflamed Breasts.—Dr. Brindeau points out that galactophoritis plays a great part in the causation of mammary abscess. The inflamed breast may have been infected through the blood or through the lymphatics, but most frequently the poison reaches the gland through its excretory ducts. Mammary abscess is the homologue of the abscesses in surgical kidney infected through the ureter. In galactophoritis the staphylococcus albus and aureus are found, but both species exist in healthy mammary ducts. Infection extends through excoriations of the nipple, through the hand of patient, nurse, or doctor, fouled with the lochia, or, most frequently, directly from the child, as its mouth is full of microbes, and coryza or more severe infantile disorders render its saliva septic. There is also, not unfrequently, inflammation of the child's fingers at the roots of its nails. About the second week the symptoms appear—the well-known earlier signs of inflamed breast. On pressure of the nipple milk exudes from some of the ducts, but pus from others. The pus is, of course, yellower and more tenacious than the milk, but suspected exudations of this kind should be tested by absorbent wool, which takes up the largest drop of milk immediately, but cannot absorb pus. That fluid, when expressed from the duct, lies on the surface of the wool in the form of a greenish-yellow drop. Sometimes a drachm or more can be expressed. The process should be repeated twice or thrice daily, and the nipple carefully washed afterward with an antiseptic solution. The child must not be fed from the inflamed nipple. If the expression of the pus be neglected abscess will follow. Suckling from an inflamed nipple does great harm to the infant. Gastroenteritis, pemphigus, and conjunctivitis are undoubtedly caused by the ingestion of pus with milk. Purulent conjunctivitis in infants is a direct cause of infection of the mother's mammary ducts.—*British Medical Journal*.

Diseases Simulating Tuberculous Coxitis.—In referring to a case under treatment in which hip disease had been diagnosed, but in which it was entirely absent, Duplay states (*New York Medical Times*) that such mistakes are by no means uncommon, and divides conditions simulating hip disease, but with the joint quite unaffected, into two groups—viz., those in which there is an appreciable lesion more or less in the neighborhood of the articulation, and those in which no local lesion exists at all. As to the first group, he mentions inflammatory states of the pelvic bones or femur, suppuration in the bursæ beneath the glutei, and neoplasms of pelvic or femoral origin. Such cases are recognized as not originating in the hip-joint by the absence of one or other typical symptoms of the disease. The main point of the lecture, however, consists in the discussion of the diagnosis of hysterical hip when there is no local lesion. It occurs naturally most in women; it often starts suddenly from some insignificant cause, and may even arise from imitation. Various deformities arise from malposition of the limb, and any of the characteristic postures may be met with, although flexion with abduction and inward rotation is perhaps the most common. The great resistance to movement is also a marked feature, since in tuberculous disease, with time and patience, one can almost always obtain a certain amount of mobility, while in the hysterical form nothing is gained thereby. The gait, too, differs in the two cases: a neurotic patient will allow herself to be moved out of bed, and can get about without pain by hopping, though still retaining the deformity; a tuberculous subject will not be able to do this. Hysterical contraction rarely leads to atrophy of the muscles, which is so marked a feature of the true joint affection. Finally, it may be necessary to anesthetize the patient in order to demonstrate the integrity of the articulation.

Disseminated Spinal Sclerosis.—Dr. Oppenheim lays stress upon the importance of various intoxications as a cause of this disease. In taking the history of these cases the previous occupations of the patients should not be overlooked. In twenty-eight of thirty-six cases treated by the author during the last few years, the history was carefully inquired into, and in eleven out of the twenty-eight the patients had long been exposed to the influence of such poisons as lead, copper, zinc, etc. Intoxications rank in the author's opinion among the most important causes of disseminated sclerosis. On the other hand, other causes must not be overlooked. Not a few cases have been known to follow upon the infective diseases, such as influenza, malaria, etc. Trauma also plays some part in causing the disease. It must not be forgotten that occasionally the first beginnings of the disease may date from childhood, and that, therefore, congenital causes may exist. The author relates the case of a painter, aged forty-eight, who had suffered repeatedly from lead poisoning. During life his disease imitated very exactly disseminated sclerosis, but after death it was found to be a combined systemic disease of the cord. There were profound vascular changes both in the cord and brain, no doubt caused by the lead poisoning. In an atypical case related by the author there was a one-sided spastic paralysis, with early and marked mental changes. Another case began in a girl aged fourteen, death occurring from tuberculosis some twenty years later. The characteristic lesions of disseminated sclerosis were found. Oppenheim adds some interesting remarks in regard to the tremor, oculo-pupillary changes, bulbar lesions, etc. The relapses in disseminated sclerosis may often be traced to definite causes, over-exertion, exposure to cold, trauma, pregnancy, or parturition.—*Berliner klinische Wochenschrift*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 17, 1896.

THE ERYSIPELAS TOXINS.

ONE by one our fondest therapeutic hopes seem doomed to the crushing process, and still that hope which springs eternal in the physician's bosom rises above the disappointments of the past, which do not deter the scientific investigator from another attempt. The time seems to have arrived for the final verdict in the case of the curative effects of the toxins of erysipelas in the cure of malignant growths. Dr. Coley's experiments and cases treated have been watched with an interest which could be called forth only by the desire to find in the toxins a cure for otherwise incurable conditions. Many times the results seemed so favorable that much enthusiasm was elicited. Surprisingly good results were shown, but a close following up of the cases has resulted again and again in disappointment. Patients looked upon as cured would sooner or later turn up in the practice of other physicians, or return to report themselves only temporarily improved.

Some months ago the whole question was discussed in one of the medical societies, and the unanimous opinion was reached that this method of cure should no longer be held out to sufferers from cancerous diseases. Subsequently, the New York Surgical Society took the matter up, and, as a result, the following conclusions were presented by Drs. Stimson, Gerster, and Curtis:

"1. That the danger to the patient from this treatment is great.

"2. Moreover, that the alleged successes are so few and doubtful in character that the most that can be fairly alleged for the treatment by toxins is that it may offer a very slight chance of amelioration.

"3. That valuable time has often been lost in operable cases by postponing operation for the sake of giving the method of treatment a trial.

"4. Finally, and most important, that if the method is to be resorted to at all, it should be confined to the absolutely inoperable cases."

And now, just as we on this side are beginning to acknowledge the inadequacy of these injections, they seem to be coming into favor abroad. Dr. Matague, of Brussels, as announced in the *MEDICAL RECORD* of August 8th, has treated fourteen cases by the mixed toxins of erysipelas and the bacillus prodigiosus, with "one complete cure." In the others there was nothing

very favorable to report. In the case of cure, the diagnosis was based wholly upon the clinical signs of cancer. The growth occurred in the floor of the mouth of an old man. It is not stated how long after cure the patient was kept under observation, to see if he remained cured. In so momentous a question we are not justified in accepting the diagnosis, in view of the fact that no histological examination of the tumor was made. When a malignant growth has advanced to that point where operative procedures are no longer to be entertained, then, perhaps, no harm may come from attempts in any legitimate direction; but to hold out the hope of cure by this or any other means in conditions which are non-curable cannot be too strongly condemned.

"NÆVUS UNIUS LATERIS."

To a physician who is not a dermatologist, and who has acquired that elementary knowledge of Latin which the average practitioner is now usually credited with, the designation *nævus unius lateris*, if it meant anything at all, would convey the impression of some kind of a *nævus* situated upon or limited to one side of the body.

In the April number of the *Journal of Cutaneous Diseases*, Dr. C. C. Ransom contributes "An Unusual Case of *Nævus Unius Lateris*;" and upon first glance at the picture of the young girl in nothing but a striking attitude the inference is drawn that the unusual feature consists in the *nævus unius lateris* being in this case *bilateralis*. Whether or not this impression was the one intended to be conveyed does not clearly appear from the text, which describes warty pigmented lesions distributed over both sides, affecting one, however, more than the other. According to von Bärensprung, one side only should be affected when this designation is employed. Turning to the latest edition of an American skin book at hand—that of Dr. Jackson—we read that *nævus unius lateris* "may be unilateral and confined to one region, or bilateral and on several regions."

The writer of the paper, therefore, has authority for his "*bilateral unius lateris eruption*;" but in all sincerity we would implore the gentlemen with dermatological proclivities to amend their nomenclature for the benefit of the outsider. The *nervus navi* of the Germans, or *ichthyosis hystrix*, or, in fact, anything, would be preferable to such a bilateral one-sided name.

A PHYSICIAN ON THE WHEEL.

UNTIL Dr. Gihon gave his opinions on the bicycle and its riders, at the recent meeting of the Public Health Association, it was thought that the only medical men who did not ride were those who lived in mountainous regions, where the hill climbing was too great, or on the seaside, where the sand was too deep. When, therefore, we speak of "Dr. Gihon on the wheel," we do it in the same sense that we would refer to "Hare on the Stomach" or "Skinner on Cutaneous Diseases." We would not imply that he had ever had a closer connection with this wonderful instrument of progress-

sion than arises from the practice of writing about it. Indeed, we are at a loss to know where, unless upon a bicycle racetrack, the writer could have gained portions of his knowledge and almost all of the inspiration which enabled him to write of "the gliding throng" of crouching forms "peering intently and anxiously with contracted brows." Now, we rather pride ourselves in New York upon our erect and manly carriage, and every wheelman who has the true interests of the sport at heart thinks of little else, while out for an afternoon turn around the now completed Grant monument, than to keep his brow smooth and his lip curled, so that no one can suggest the presence of the so-called bicycle face.

Accidents happen to devotees of the new sport, and the perineum may come in for a due proportion of resulting injuries; but the alarm the gentleman feels that the number of genito-urinary specialists now existing may be far too small for the demands of the immediate future, because of injury inflicted upon this region, we believe groundless. In point of fact, those who confine themselves largely to this branch of surgery find more leisure than ever for their own bicycle exercise, as Dr. Gibon may convince himself any fine day he will take a cab and drive up the Boulevard.

PARALYSIS FOLLOWING ANÆSTHESIA.

THE mere possibility of death occurring from the administration of an anæsthetic is so appalling to the mind that it is liable to make one forgetful of certain other occasional accidents which would be considered very serious if they were to take place under different circumstances. Among these lesser and rather rare but really serious accidents, is that of paralysis of certain groups of muscles. This paralysis may be central or peripheral in origin, temporary or permanent in duration. It may not occur sufficiently often to attract the attention of those who only occasionally give an anæsthetic, and when it does take place the relation of cause and effect may seem too obscure to excite more than suspicion.

In a paper read at the recent meeting of the French Medical Congress, Vautrin related three cases of post-anæsthetic paralysis—one involving the right deltoid, biceps, and brachialis anticus; the second involving the right deltoid and long supinator; the third affecting the face. Only the first had remained permanent. In two it is stated that chloroform was the anæsthetic used. The author comments upon the fact that the paralysis is nearly always of the right brachial plexus, but it may affect the face or the tongue, and is often accompanied by ocular trouble—dilatation of the pupil, amaurosis, etc. It may be observed just after the patient awakes from anæsthesia, or not until hours or days afterward. Sometimes there is partial loss of sensation, but this soon passes off. Certain German writers have designated it chloroform paralysis, but chloroform is not always the anæsthetic employed. Two forms are to be recognized—one of peripheral, the other of central origin. The first is the more frequent, the arm being the part usually affected. Büdinger

attributes it to pressure on the brachial plexus, especially when the arm is elevated to facilitate operations on the breast and abdomen. Traction on the arm or shoulder may produce the same result. But this cannot be the explanation of some cases in which no such pressure has been exerted, and for these Vautrin suggests a toxic origin provoked by the anæsthetic. The paralyzes of central origin are due to cerebral hemorrhages favored by the struggles of the patient during the period of excitement.

News of the Week.

Mothers and Babies' Hospital.—Dr. J. Carlisle DeVries has been appointed resident house physician of the Mothers and Babies' Hospital in connection with the New York Polyclinic.

Dr. George B. O'Sullivan died on October 11th, at his home in Brooklyn. He was born in 1866, and was graduated in medicine from the Long Island College Hospital in 1887.

The Plague in Bombay.—Between October 2d and 7th ninety-seven cases of the bubonic plague were reported, and since the beginning of the epidemic two hundred and seventy-six deaths have occurred. A quarantine against Bombay has been declared at Aden and at the Egyptian ports.

Academy of Medicine.—In the section on general medicine, October 20th, there will be a demonstration upon patients of the phonendoscope. On October 28th, in the section on laryngology, photography of the larynx will be illustrated by a lantern exhibition and demonstration of apparatus.

The Flower Hospital Annex.—The new building erected as an annex to Flower Hospital, at East Sixty-third Street and the Eastern Boulevard, was occupied by patients for the first time on October 12th. In it are three large wards, one of which is for women. There are also fourteen private rooms.

Physician's Wife Injured in a Bicycle Accident.—The wife of Dr. Lorenze, practising at 1,658 Lexington Avenue, was severely injured in a collision with a carriage on October 10th, at Bronxdale. The driver of the colliding vehicle tried to escape, but has been arrested.

The Bicycle in First Aid to the Injured.—A suggestion made a year or more ago by the MEDICAL RECORD was shown to be of practical utility a few days ago in a bicycle accident in this city. One of the first to reach the unconscious wheelman was a mounted policeman (on his wheel). Acquainting himself with the serious nature of the case he immediately remounted and sent in an ambulance call from the nearest box. Before the spectators had time to realize that any proper steps were being taken, a surgeon with the red cross of his calling upon his sleeve arrived upon his bicycle and took charge of the case, while the ambulance to which he belonged followed with the lesser speed of horse-power propulsion.

Spanish Losses in Cuba.—It is estimated in Madrid that, since the beginning of the Cuban revolution, the army of occupation has lost nearly fifty thousand men, of whom by far the greater number died from disease. The total number of patients in the military hospitals on one day recently was 9,475, of whom 1,035 were suffering from yellow fever, 1,331 from malaria, and 520 from wounds.

A New Serum.—This one comes from Bogota, where Dr. Juan de Dios Carrasquilla has injected kids and horses with leprous blood and with the serum from these animals has treated lepers. A report made to the New York Academy of Medicine shows decided improvement in the patients, such as return of sensitiveness to skin areas, resorption of tubercles, cicatrization of ulcers, and, more than this, no development of new lesions in some patients.

The Brooklyn Naval Hospital.—Secretary Herbert has adopted the plan submitted in competition by Mr. Smithmeyer, the designer of the Congress library, for the new ward of the Brooklyn Naval Hospital, and in a few days will invite proposals for its construction within the \$50,000 appropriated by Congress. The plans call for a structure of white brick and marble, of classic lines, designed in accordance with the most approved modern practice at home and abroad in public hospitals.

The Roentgen Rays in Nature.—At the recent meeting of the British Association for the Advancement of Science, Dr. Dawson Tucker stated that the ordinary glowworm emits α -rays which will pass through solid bodies, even a thin sheet of aluminium. It is probably not the visible light from the insect which does this, for Dr. Dawson Tucker in his experiments had a good deal of difficulty in getting the worms to glow, but he found that even when not visibly glowing they gave off a radiation which affected the photographic plate.

Prosperity of the Dispensaries.—Private practice in and about New York is reported to have been unusually quiet during the early fall. Not so in dispensary service. During the month of September 124,081 patients were treated at the outdoor department of Bellevue, against 92,434 in September, 1895—an increase of twenty-five per cent. The factors accounting for this would seem to be hard times, increase of poverty, and a tendency on the part of the frugal minded to save on the doctor's bill.

Dr. Hamilton's Conflicting Duties.—In speaking of the recent order of the marine hospital service, transferring Dr. Hamilton, the editor of the *Journal of the American Medical Association*, from Chicago to San Francisco, the *Medical Standard* says that the transfer was made in direct violation of the promise of the supervising surgeon-general to Dr. Hamilton that he should have at least two terms in Chicago, and it is apparently for personal reasons, rather than for the good of the service. Dr. Hamilton promptly appealed to the secretary of the treasury, but the latter has declined to interfere in the matter. The *Medical Stand-*

ard intimates that personal reasons or jealousy, rather than the needs of the service, are responsible for the transfer. The *Journal* has persistently opposed the scheme to convert the marine hospital service into a department of public health. Possibly, therefore, it is thought that the needs or the ambitions of the service would be promoted by the removal of the editor to another sphere of usefulness.

Died in the Doctor's Office.—It is always a regrettable occurrence for a physician to lose a patient at his own office. When death results from an anæsthetic administered or as a consequence of an operation performed, the disquieting features are the more pronounced. In the case of Dr. Bosburg's patient, who died of apoplexy or heart disease in his physician's waiting-room on Sunday last, no reflection can possibly be made upon the doctor, since he was not at home when the unfortunate accident happened. Medical assistance was, however, required, not only for the daughter of the patient, who had accompanied him and who became hysterical, but the physician's daughter, having been ill for some time, was prostrated by the shock, it is said, and her condition rendered serious.

Tuberculous Cows Destroyed.—A report has been made by Chief Inspector Martin upon the sanitary condition of all cows within the city limits, and the condition of the premises where they are kept. Below the Harlem there are one hundred and sixteen different locations, in which a total of three hundred and forty-three cows are stabled. Out of one hundred and fifty-three examinations made with the tuberculin test, twenty-eight tuberculous cows were found and destroyed. The post-mortem examination confirmed the test in every single instance. The health of a large number of persons has been in danger from the milk supplied from these sources, and it is sincerely to be desired that the work thus entered upon may be pursued until it becomes no longer possible for so many diseased animals to exist at any time, either within the city's limits or in herds from which the city's milk supply is drawn.

College of Physicians of Philadelphia.—At a stated meeting of the section of otology and laryngology on October 6th Dr. E. B. Gleason described a new operation for the correction of deflection of the nasal septum and exhibited four patients in whom the procedure had been carried out successfully. Drs. E. L. Vansant and M. B. Miller reported conjointly a case of carcinoma of the antrum of Highmore, apparently originating from the alveolus of the upper jaw, with such extensive recurrence after operation as to preclude hope of success even from excision of the entire superior maxilla. Dr. A. W. MacCoy made a preliminary communication dealing with certain pathologic conditions of the fossæ of Rosenmüller and the Eustachian tubes. Dr. Harrison Allen related the case of a girl in whom a copious white deposit of uncertain nature reappeared upon the tonsils after removal, in the absence of local evidences of irritation other than pain and of constitutional manifestations.

Dr. E. B. Gleason presented a specimen of cystic polypus removed from the pharyngeal aspect of the nasal septum. At a stated meeting of the college on October 7th Drs. W. J. Taylor and C. W. Burr reported conjointly a case of sarcoma of the medulla oblongata unattended during life with changes in the eye-grounds. At a meeting of the section on general surgery on October 9th Dr. Randolph Farles demonstrated a modified form of antero-posterior brace for the treatment of Pott's disease, in which the pressure is diverted from the spinal column and undesirable pointing of abscesses avoided.

Protest against Senate Bill 1,552.—The American Association of Obstetricians and Gynecologists assembled in annual session in Richmond, Va., September 22-24, 1896, desires to present to the Congress of the United States a protest against the passage of Senate bill 1,552.

Whereas, The enactment into law of the specified bill would greatly interfere with and retard the investigations that are at present being conducted at Washington by the laboratories connected with the Marine Hospital, the offices of the surgeon-general of the United States army and navy, and the bureau of animal industry of the department of agriculture; and

Whereas, The results of their investigations have been of immense importance to the health and wealth of the people of the country; and

Whereas, More brilliant results are promised for the near future in connection with preventive medicine and the health of men and animals;

Therefore, be it Resolved, That this association protests against the proposed legislation by Congress which has for its object the restriction of animal experimentation in the District of Columbia, and, while opposing needless cruelty and experiments upon animals in the public schools, this association considers that those who are trained in the special line of research necessary for the conduct of the work referred to are the ones best able to decide upon the advisability and utility of animal experimentation, and should not be hindered in the prosecution of their humane work.

Resolved further, That a copy of these resolutions be sent to the members of the House and Senate of the United States Congress and also to the President of the United States.

Schuylkill County (Pa.) Medical Society.—At a meeting of the Schuylkill County Medical Society, held at Pottsville on October 6th, Dr. G. H. Halberstadt delivered an address on surgery, Dr. George Farquhar read a paper on "Chronic Endometritis," and Dr. Wendell Reber reported a case of spinal disease attended with blindness. Dr. Joseph M. Spellissy reported "A Death during the Administration of Ether," in a case of umbilical hernia operated upon after symptoms of intestinal obstruction had existed for five days, and in which not more than one ounce of the anæsthetic had been most cautiously used. After death degenerative changes were found in heart and kidneys. Drs. J. William White and A. C. Wood read a joint paper, entitled "Some Recent Cases of Renal Surgery," detailing twelve cases of various kinds—ab-

cess, tuberculosis, calculus, hydronephrosis—all successfully operated on, although death occurred in one case two years after the operation, as a result of amyloid disease from protracted suppuration. Dr. John B. Roberts reported "A Successful Operation for Cleft of the Soft and Hard Palates," and exhibited the patient; and Dr. G. Hudson Makuen described the steps by which the movements of the tongue were increased and improvement in speech brought about by manipulation and exercise.

The Seventh Italian Medical Congress will be held in Rome, on October 20th and subsequent days, under the presidency of Dr. Baccelli.

The Cholera Epidemic in Egypt during August was of an unusually fatal type. Cairo returns show that of 4,816 cases, 4,004 were fatal.

Dr. William Mabon has been invited to the superintendency of the Ogdensburg Insane Asylum in place of Dr. Wise, who was appointed State lunacy commissioner. Dr. Mabon is now superintendent of the Willard Asylum. Before he went there he was the first assistant at Utica.

Medical Women in Turkey.—It is stated in *The Hospital* that the gentle Sultan of Turkey has forbidden women physicians to attend upon his subjects, and that Dr. Grace Kimball, who had established herself with success in Turkey and worked there for fourteen years, has now returned to London.

"**La Revista de Medicina y Cirujia**" is the title of a new journal published in Havana, under the editorial supervision of a committee of physicians. The first number is dated September 10th. The secretary of the editorial committee is Dr. José A. Presno.

American Dentists Not Wanted in Germany.—A dentist was recently arrested and fined in Berlin, for displaying upon the door of his office a plate describing him as a doctor of dentistry, with a diploma granted by an American dental college. The court held that it was against the law for him to use a foreign title in practice in Germany.

Vital Statistics of Newark.—Twenty-five of the seventy-six deaths reported in Newark during the week ending October 10th, were from infectious diseases. The number of cases of infectious disease reported was fifty-two—ten of typhoid fever, eight of scarlet fever, and thirty-four of diphtheria.

The Health of the Army.—In the report of the surgeon-general of the army for the year ended on June 30th it is stated that the health of the army was better last year than ever before. Dr. Sternberg writes: "All the rates that are usually considered by statisticians as throwing light on the physical condition of a community have been lower than in any previous year of the recorded history of our army. The number constantly sick was 33.89 per thousand of strength, as compared with 34.49 during 1894, and 41.87 as the average annual rate of the preceding ten years. The mortality rate from all causes was 5.16 per thousand of strength, as compared with 6.69 in 1894 and 7.85 for the preceding decade. The lowest previous rate was 6.35, in 1889."

Bovine Tuberculosis in San Francisco.—It is stated that nearly fifty per cent. of San Francisco's dairy cows will have to be slaughtered to stamp out tuberculosis.

Medical Study in New Zealand.—A bill has been introduced into the legislature of New Zealand which will lengthen the course of study necessary for a degree in medicine from three years, as at present required, to five years.

The Jenner Centenary in Russia, which was postponed from May to October, on account of the Tsar's coronation, has been put off for another month for the reason that his imperial majesty is out of the country. It is now hoped that the ruler's movements will permit the celebration to take place on December 3d.

Loss of Life in the Fishing-Fleet.—A summary of the disasters among Gloucester fishermen for the year just ended shows that seventy-four lives have been lost, against an average of ninety-nine for the twenty-two years previous. The number of vessels lost was thirteen.

Bovine Tuberculosis in New York City.—The board of health is making a thorough inspection of all milch cows kept within the city limits in order to exterminate tuberculosis. Of three hundred and eight animals which have been examined by the tuberculin test fifty-two have been found diseased and have been killed.

Norristown (Pa.) Insane Hospital.—Dr. Alice Bennett, after a service of sixteen years as chief of staff, resigned her position. The trustees showed their appreciation of her valuable services by passing appropriately complimentary resolutions.

Addition to a Hospital.—A new annex to the Samaritan Hospital of Philadelphia was opened with imposing ceremonies on September 26th. Several addresses were made and a memorial stone was placed in position. The addition to the hospital has been erected at a cost of \$10,000, collected by subscription. The new building is three stories high, fifty-eight feet deep by forty-four feet wide, and will accommodate twenty-two additional beds. It contains on the ground floor an accident ward, a bathroom with a cemented floor and provided with a portable bathtub, a waiting-room for patients, a kitchen, a drug room, and a maternity ward; on the second floor a children's ward, a ward for men and one for women, and a commodious, well-lighted operating-room; and on the third floor are quarters for the nurses. A sterilizing plant costing \$500 has been introduced and is capable of sterilizing enough water for all the needs of the hospital. A training-school for nurses will be organized. The hospital has been further enriched by the donation by Mr. P. A. B. Widener of a pair of fine horses for ambulance purposes. Dr. W. F. Haehnlen is physician-in-chief to the hospital.

Pathological Society of Philadelphia.—At a stated meeting of the Pathological Society of Philadelphia, on October 8th, the following officers were elected for the ensuing year: *President*, Dr. J. H. Musser; *Vice-Presidents*, Drs. John Guitéras, William E. Hughes, F.

A. Packard, C. W. Burr; *Secretary*, Dr. A. A. Eshner; *Treasurer*, Dr. T. S. Westcott; *Recorder*, Dr. W. S. Carter; *Curator*, Dr. D. Riesman.

Faith Curists Called to Account.—The coroner of Scranton, Pa., after investigating the death from diphtheria of a boy who received no other therapeutic consideration than the prayers of Christian Scientists, held the boy's father and two other faith curists for criminal neglect, and the district attorney has issued warrants for their arrest.

Epidemic Disease in Pennsylvania.—Typhoid fever is extremely prevalent in Chester County, although the number of deaths is not yet large. Diphtheria of a virulent type prevails at Harwood, a small mining town, two miles west of Hazelton. Hog cholera of a fatal character has appeared in Smithfield Township, Monroe County, and is causing considerable anxiety among the farmers.

Association of Lehigh Valley Railway Surgeons.—The seventh annual meeting of the Association of Lehigh Valley Railway Surgeons was held at Bethlehem, Pa., on October 6th. Dr. J. G. Zern, of Lehigh-ton, delivered an address; Dr. Frank D. Dowe, of Rochester, read a paper on "Untoward Factors in Traumatic Surgery;" Dr. G. R. Trowbridge, of Buffalo, one on the "Treatment of Fractured Clavicle by Means of the Dowel Pin;" Dr. C. R. P. Fisher, of Bound Brook, one on "Sprains;" Dr. L. E. Hollister, of Newark, one on the "Conservative Treatment of the More Severe Injuries of the Extremities, Particularly the Joints."

A Surgeon Disciplined.—The Columbus Academy of Medicine recently censured one of its members for violation of the code of ethics in permitting the publication in a daily paper of the report of an operation performed by him. The report was accompanied with a picture of the operator. The charges brought against the surgeon were three: First, that while conducting an operation at the clinic of the Ohio Medical University he had permitted a layman to be present and witness the operation and hear the lecture on the same; second, that he had revised the manuscript of the article which was published; and third, that he had erred in not withholding the article from publication while it was in his possession. The committee in charge of the trial found the accused guilty of the charges as presented, but it is claimed by the surgeon's friends that no censure was implied in this finding. The chief stress was laid upon the fact that a layman was allowed to be present at the operation.

Responsibility of Hypnotists.—Judge Foute, of Atlanta, has rendered a decision holding that the hypnotist is directly responsible for the acts of his subjects. During a performance at a local theatre a hypnotic subject grabbed a hat belonging to a man in the audience and bit a piece out of it. The man giving the exhibition and his business manager declined to make good the cost of the hat, and the hypnotist was prosecuted before Judge Foute upon a charge of malicious mischief. The judge sustained the charge and bound the defendant over to a higher court.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, October 8, 1896.

WALTER LESTER CARR, M.D., CHAIRMAN.

Congenital Stenosis of the Pulmonary Valves.—

The evening was devoted to the presentation of cases. DR. HENRY KOPLIK said he had the rare opportunity of presenting two cases illustrating the extremes, so far as the symptoms were concerned, of congenital stenosis of the pulmonary arteries. The first patient was an infant, eight months of age. The mother stated that the labor was a severe one; forceps were used. She did not see the babe until it was nine weeks old, when she noticed that when it cried it became blue. The skin then was of grayish color, and the extremities even in summer were cool and below the normal temperature. On percussion Dr. Koplik found nothing abnormal about the heart, but on auscultation he could hear a distinct rasping murmur over the second intercostal space to the left of the sternum, conducted to the apex and also to the base of the heart. The ends of the fingers and toes were slightly bulbous. It was not what was called a blue baby, but only at times became cyanosed.

The second case was that of a boy, aged sixteen years, who up to the fourth year was healthy. Then, after gastro-intestinal disturbance, he became blue and even in the summer the extremities were cool. At the present time the boy was markedly blue, the conjunctivæ and lips showed cyanosis, the surface temperature was below normal, the extremities of the fingers and toes were bulbous; on exertion he had attacks of great dyspnoea. There were frequent attacks of headache. In this case, in addition to the loud murmur over the second intercostal space to the left of the sternum there was dilatation of the heart. It was not unlikely that there was, besides stenosis of the pulmonary valves, a patent foramen ovale.

The discussion on these cases took place after others had been presented.

Arthritis Deformans.—DR. W. L. STOWELL presented a girl, nine years of age, and photographs taken at different periods, illustrating arthritis deformans. There was no family history of rheumatism and in other respects it was negative. The patient's trouble dated from an illness in the summer of 1893 when she had fever and chills for two weeks. She then had much lameness of the feet, and a month later the joints of the hands and wrists became involved, and within three months the elbows and knees were swollen. She was in a hospital three months, and in the fall of 1895 was sent to Randall's Island Hospital, at which time the head was immovable and nearly rested upon the sternum; the shoulder-joints were semi-ankylosed; the elbows semi-flexed and enlarged; the wrists enlarged, tender, and almost motionless; the metacarpal and carpal joints stiff, the hips fixed, the knees much enlarged, the ankles thick, tender, and stiff, and the foot was partly extended. The muscles were atrophied. There was no evidence of visceral trouble. The condition had been stationary for nearly two years until some months since, when in addition to medicinal treatment the nurse began patiently and systematically to carry out massage and encourage voluntary movements, including attempts at walking. The improvement had been striking, but all the joints were still more or less enlarged and stiff, and the muscles atrophied. The medicinal treatment had included from time to time iodide of potassium, wine of colchicum, cod-liver oil, iron, hypophosphites, and

strychnine, but the improvement was attributed for the most part to massage, motion, and hot baths.

In a brief review of the literature of arthritis deformans it was stated that Dr. J. G. Mitchell regarded it as neurotrophic entirely, and Dr. Osler agreed with him. There was no evidence that gout or rheumatism predisposed to it.

Progressive Muscular Atrophy.—Dr. Stowell presented a girl, aged thirteen years, with progressive muscular atrophy, which began, it seemed, after an attack of diphtheria when she was at the age of five years. The family history was negative except that one uncle committed suicide during an attack of melancholia. About a month after she had had diphtheria the parents noticed that the patient's face began to get smooth, lose its folds and expression; later the eyes could not be closed tightly; she could not whistle; within a year she would stumble easily; the muscles of the arm wasted, but the forearm had remained well to the present time. All of the muscles of the back and shoulders had wasted greatly. The gluteals were well developed. The author quoted Sachs to the effect that the several types of progressive muscular atrophy—the facial, the scapulo-humeral, and the pseudo-hypertrophic—were the same disease. Out of forty-nine autopsies thirty-four showed lesions of the spinal cord, so that the weight of evidence was in favor of its being due to a central lesion. The treatment had been tonic, including iron, strychnine, quinine, and arsenic, but the disease had progressed constantly.

Progressive Muscular Dystrophy.—DR. CHARLES E. NAMMACK presented a man aged twenty-six; family history negative except that his mother had died of phthisis. The patient remembered no illness, denied syphilis, but admitted free use of alcohol before the commencement of his present trouble. Eight years ago he began to have sensations in the back as of over-tire. Seven months later the shoulders began to diminish, the muscles wasted, and three years later the muscles about the hip and thighs began to waste and he lost power to walk. There was no muscular twitching and no sensory disturbance. The man's occupation threw some light on his disease, he having been a public contortionist. The disease had advanced so far as to render him almost helpless.

Progressive Muscular Atrophy.—Dr. Nammack presented a colored boy, about nine years old, with commencing muscular atrophy or pseudo-muscular hypertrophy. Three months ago the mother noticed that he was disinclined to stand, and about a week ago he began to stumble and fall easily. The shoulder muscles showed greatest atrophy, but those of the back were also weak, permitting of marked antero-posterior curve of the spinal column. The thigh and calf muscles were large, presenting apparently pseudo-muscular hypertrophy. The neck and arm muscles also showed wasting.

Arthritic Muscular Atrophy.—Dr. Nammack presented a third patient, a boy of about thirteen years, who was said to have had rheumatism three years ago, affecting the right elbow and shoulder. The atrophy seemed to have been limited chiefly to the supraspinatus and infraspinatus of the one side. It was an interesting fact that since the mother had begun to rub the region (with soap liniment) in September the atrophy had largely disappeared.

Rachitic Muscular Atrophy.—DR. H. D. CHAPIN presented an infant, fifteen months old, which had been well up to the sixth month, and then it was noticed that the head seemed too heavy for the body. It became very irritable, and at times would lie in a semi-comatose condition. There was flattening of the occiput, the muscles of the body were very weak, but seemed not much atrophied. Dr. Chapin thought the case was one of rachitis, a disease which manifested

itself in various forms, in some instances the muscles being most affected.

Cardiac Disease; Epistaxis.—DR. KOPLIK presented a girl of about seven years, who at about the age of two years began to have attacks resembling rheumatism, with fever and pain in the joints. These attacks recurred nearly every year. Later she began to have attacks of very persistent nasal hemorrhage, recurring at intervals of a week, a month, or several months. The last hemorrhage threatened life, and left her nearly exsanguinated, but finally ceased of its own accord. The child was still anæmic. Examination of the heart showed double mitral lesion and dilatation of the left ventricle, and possibly also of the right.

Early Enlargement of the Liver.—DR. THOMAS S. SOUTHWORTH presented a boy of five years, with enlargement of the liver, which he attributed to fatty infiltration. There had been four other children in the same family, of whom one had died of tuberculous meningitis, one of gastro-intestinal fever, one was feeble-minded. The patient presented had always had a large abdomen, and when a baby had diarrhœa, was in a condition of marasmus, and was given brandy. The abdomen continued to increase in size, which increase at the second year was attributed to sarcoma of the kidney; but this was proven not to exist. Before coming under Dr. Southworth's observation at the fourth year, the boy had convulsive seizures, which had been pronounced epileptic. Under treatment directed more particularly to the gastro-intestinal tract, the convulsive seizures had ceased and the patient had improved; yet during the past summer he had had occasional attacks of fever, vomiting, pain in the abdomen, slight jaundice, sometimes diarrhœa. There was purulent otitis media. In connection with the etiology of the fatty liver, mention was made of the use of starchy food, as well as of brandy during infancy.

The Treatment of Cretinism.—DR. KOPLIK presented two patients and reported progress on the treatment of cretinism. The patients were about three years of age, and had been under treatment over a year. When first seen the signs of cretinism were well-marked—dwarfish appearance, protuberant abdomen, thick lips, thick tongue, flattened nose, cedematous eyelids, dull appearance. One patient had abscesses; rectal temperature, 96° F.; extremities blue; hæmoglobin, twenty-five per cent. The treatment had been use of thyroid extract. When the patient was last shown, a year ago, the percentage of hæmoglobin had risen from twenty-five to forty-five, and at present was seventy-five. In the other case there had been a similar rise from eighteen per cent. He had been told by Dr. West that the original dose of thyroid could not be adhered to as the children grew older: they should be kept on just as large doses as they could stand. Notwithstanding there had been marked improvement, he thought his patients would become still brighter under larger doses of the thyroid.

DR. J. P. WEST, of Ohio, presented by invitation photographs of the case of cretinism treated with such success with thyroid, and reported by him in the *Archives of Pediatrics*.

DR. W. P. NORTHRUP congratulated Dr. West on the success attained in the treatment of his case of cretinism. He had himself treated two cases by thyroid, and was able to bring them up to a certain point of improvement; but they would return again to their former condition. He had thought a change of the proportion of thyroid might help, but the relapses continued to take place.

DR. WEST said that after nine months' treatment he was able to increase the dose, given twice a day, to a grain and a half, and within a year the girl grew eight and one-fourth inches and gained fourteen

pounds. At one time the thyroid was left off three months, and there was a relapse. He thought it advisable to increase the amount whenever relapse threatened.

Congenital Cyanosis and Cerebral Abscess.—Discussion of the several cases being in order, DR. NORTHRUP said, with regard to congenital narrowing of the pulmonary arteries, that two cases of "blue baby" had appeared at the foundling asylum about two years ago, and, on turning to Dr. J. Lewis Smith's book on "The Diseases of Children," they concluded that the lesion must be congenital narrowing of the pulmonary artery and defect of the septum ventriculorum. In the same book it was stated that many such subjects, surviving the second year up to the twenty-fifth year, died of cerebral abscess. One of the patients had whooping-cough, and they expected then soon to confirm the anatomical diagnosis; but the patient survived, and also passed successfully through an attack of measles. It was then expected to live indefinitely, but one day was found blue, delirious, and stupid. They made the diagnosis of cerebral abscess. Autopsy revealed congenital narrowing of the pulmonary artery, defective septum ventriculorum, and cerebral abscess. They expected a similar result in the second case, but the child was still living. One of the physicians connected with the Presbyterian Hospital in the neighborhood, who was interested in these cases, met a young man on the street whose face and hands were blue, and ventured to ask him some questions and received the promise of a visit to the hospital, where he could be examined. He did not, however, come on the appointed day, but later was brought in delirious and with symptoms pointing to cerebral abscess. As in the cases presented this evening, and in Dr. Northrup's, there was a purring thrill at the second costal cartilage on the left, pointing to the diagnosis already suspected to exist. Autopsy revealed narrowing of the pulmonary artery, defective septum ventriculorum, and cerebral abscess. Dr. Northrup said two similar cases had been reported at the recent meeting of the American Pediatric Society.

DR. MARY PUTNAM JACOBI remarked that not all of these subjects died of cerebral abscess, for she knew of one "blue" young man, who at the age of twenty-four went to Spain for the advantages offered by the climate, and after remaining two years died of the fever of the country.

DR. E. D. FISHER regarded the case of the man presented by Dr. Nammack as a typical one of progressive muscular atrophy of hereditary type. Such cases commencing in youth, whether of the scapulo-humeral or other form, were, as a rule, of hereditary taint, and were quite distinct in their course and in their pathology from the progressive muscular atrophy of spinal type. In the former no lesion was found in the spinal cord. He had shown this man to classes at the University Medical College the past two years, and regarded the case as typical, but had not been able to obtain a history of hereditary taint. The subject belonged to a family of acrobats, and it was not unlikely this career had had something to do with his disease. As long as the muscular atrophy was not complete, there was always some electrical reaction. In his experience there was rarely complete reaction of degeneration, but there might be partial reaction.

DR. FISHER said, in relation to Dr. Northrup's remarks, that he knew no reason why there should have been abscess of the brain, unless some lesion in the heart should cause septic abscess.

DR. FREDERICK PETERSON thought the colored boy had not pseudo-hypertrophic paralysis, although there were some of the symptoms of that disease. The gait was rather a spastic parietic gait, the knee jerks were much exaggerated, there was ankle clonus—symptoms

pointing to a lesion in the pyramidal tracts, probably somewhere in the cord. Furthermore, there had been some incontinence of urine and some rigidity of the neck muscles. There was weakening and wasting of the muscles of the arm, without loss of power in any particular muscle. Everything pointed rather to a lesion in the cervical cord, yet in the short examination made he would not pronounce that a final diagnosis. The statements of Dr. Northrup had interested him very much. He had never before heard of the frequent connection of abscess of the brain with cyanosis. The pathological relation would make an interesting study. As a rule, the differentiation between atrophies and dystrophies was not difficult. The atrophies were generally called spinal, the dystrophies were primarily muscular. In the latter the muscular fibres, as a rule, underwent degeneration at an early period of life. The differentiation was made by about four symptoms: In the spinal form of progressive muscular atrophy there were atrophy and fibrillary tremor, no heredity, no hypertrophy, presence of reaction of degeneration. In dystrophy there was heredity, atrophy with hypertrophy, no fibrillary tremor, no reaction of degeneration. As long as any of the muscle remained, it reacted in the normal manner. Dr. Peterson had never seen even partial reaction of degeneration in such cases.

DR. J. L. SMITH remarked, with regard to cerebral abscess referred to by the last two speakers, that he did not remember having attempted to give an explanation of its occurrence. The case of the colored boy seemed to him one of incipient pseudo-hypertrophic paralysis, as stated by Dr. Nammack.

DR. DESSAU mentioned a case of arthritis deformans of perhaps three years' duration, in a patient of six years, which had not improved under hydrotherapy, etc.; but he would now apply massage, in view of the success obtained with it by Dr. Stowell.

Clinical Department.

UTERINE FIBROID AND PREGNANCY.

By FRANK L. BURT, M.D.,

BOSTON, MASS.

PREGNANCY and uterine fibroid are associated sufficiently often to occasion little if any comment, and might call for nothing more than ordinary ability and good judgment in the way of making a good differential diagnosis. The following case is of sufficient importance for record as a surgical case on its own merits, but is doubly interesting because of a condition of accompanying pregnancy which is unique from a surgical and embryological standpoint.

Mrs. T—, colored, was brought to me in September, 1895, and history and examination were as follows: Aged thirty-six; twice married, covering a period of ten years. She had had no children and no miscarriages, and pregnancy was considered as impossible. A small bunch was developing in the pelvis, which she first noticed about ten years ago. Its growth was gradual and constant. She was especially troubled in the left groin, having considerable bearing-down, which increased to severe pain at the menstrual period. There was at this time very little flow. Backache was constant and more or less severe. The bowels were interfered with by pressure. Added to these symptoms, which gradually became more severe, were those from frequent inflammatory attacks, which confined her to bed for two or three weeks at a time and resulted in the production of adhesions. She had managed to work, except at these periods. The menstrual flow, which was always small, began to grow less in March, 1895, and was still less in April, May,

and June. There was very little in July, and none in August. On June 10th she left her home in New York for Bar Harbor, to fill a position for the summer. Taken sick late in August, an attempt was made to move her home, but she could not get beyond Boston.

On September 6th, lacking three days of thirteen weeks since she left home, I operated on her. Her condition was such that to operate or not to operate was a serious question, although I considered that she had a very favorable chance, notwithstanding the fact that her case had been pronounced inoperable by several expert surgeons and had been refused at large hospitals of reputation. I decided to perform abdominal hysterectomy. The uterus occupied the whole of the abdomen, extending up under the ribs and pressing on the chest organs. It was absolutely immovable. I incised to the umbilicus. I found the growth flattened (spleen shaped), and strongly adherent over the whole anterior wall. After breaking down these adhesions, the top of the tumor was felt as high as the hand could reach. It was manipulated so as to draw the top of the growth out from the cavity. Below there was an extensive adhesion to the omentum, about fifteen inches in length and supplied by numerous vessels as large as a pencil. The vessels were tied and adhesions cut away.

After the tumor had been pulled out, the breathing was greatly relieved. A rubber tube was drawn around the stump, as low as possible in the pelvis. I incised the growth just above the tube, and, strangely, out popped an ovum sac, very small, containing very little fluid, and, to judge from a macroscopical examination, it could not be of more than eight weeks' development. The stump was treated extra-abdominally in the usual manner. Loss of blood was little, and the shock was not great. Recovery was perfect.

It is interesting to ask how it could be that a woman, married twice and for a period of ten years, with no previous pregnancy, could have become impregnated at this late date and under these conditions. How was it possible for those unhealthy ovaries to develop an ovum which could bear fruit? And how could an ovum pass through those unhealthy, adherent tubes, and the heavy, dense, large fibroid growth, so as to deposit itself and pregnancy result? The process could not have gone on to any great length. The fœtus would probably have been thrown off by pressure, or would have died *in utero*, with its consequences. It was probably removed at about the right time.

The embryo shows points of great interest, as will be seen from the report on the examination made by Prof. J. S. Flagg, as given below:

"September, 1895, Dr. Frank L. Burt, of the Union General Hospital, Boston, handed me an embryo, which on the day previous he had removed from an uterine fibroid of some seventeen pounds' weight. Examination revealed these facts: Age of embryo, slightly over twelve weeks. Weight of embryo, with amnion only (emptied, yet fresh), forty-six grains. Length of embryo, one and nine-tenth inches. Chorion thin and imperfectly tufted. Development of fœtus uneven, especially in sense organs and all fissure unions. Amnion perfect, false amnion not united well to chorion. Placenta not well formed, and associated tenuity of umbilicus. Whole embryo showed evidence of deficient nutrition, and in general appearance was like a fœtus of eight weeks."

The Physicians in Belgium at the beginning of the year 1895 numbered 2,965. The proportion of doctors to population was one in 2,100. In addition to these there were 2,394 midwives, 1,828 pharmacists, and 522 veterinarians.

A CASE OF UNILATERAL BRONCHOCELE
WITH MYXEDEMA.

BY FRANK D. MERRITT, M.D.,

BROOKLYN, N. Y.

THE case that I herewith report is of interest because it differs from any case of either goitre or myxedema that has come to my notice.

Mrs. F——, aged thirty-eight; born and resided in Westchester County, N. Y., until five years ago; since then in Brooklyn. Her history up to the time of the birth of her first child, which occurred seven years ago, presents nothing worthy of note. The labor was a difficult one, requiring the application of forceps. Two years later she gave birth at term to a still-born infant. The cause of death I am unable to learn. Since that time she has had two miscarriages, believed in both cases to be at about the fourth month of uterogestation.

On March 6th she presented herself for treatment, complaining of a swelling in the neck, which she stated had existed since the birth of her first child, seven years before, and which was increasing in size so that it was beginning to interfere with her respiration. She complained of violent headaches of almost daily occurrence, and loss of memory, and stated that she was fearful lest she was about to lose her reason. She was extremely nervous; speech was slow and hesitating; expression was dull, the eyes having a watery look; the nose and lips were thickened, the face and ankles œdematous; the skin was very dry and the hair thin and lustreless.

Upon examination I found a firm mass on the left side of the neck, extending from near the median line a distance of about seven centimetres, and measuring from above downward about five centimetres, the lower border extending slightly below the left clavicle, moving with the larynx when the act of deglutition was performed. The skin over it was freely movable. There was no perceptible abnormality on the right side of the neck. Heart normal; pulse small, frequency 84; temperature, 97.8° F. Urine normal; specific gravity, 1.016. Exophthalmos entirely absent; tongue slightly coated.

In answer to my questions the patient admitted that she suffered from habitual constipation and drowsiness during the day, with inability to sleep soundly at night. She did not sweat even when undergoing severe exertion. I prescribed a five-grain tabloid of thyroid extract, twice daily an hour after eating.

March 10th.—The patient has neuralgic pains in the lower extremities; otherwise her condition reveals no change.

March 18th.—The bronchocele is greatly reduced in size; dyspnœa is lessened; there have been no headaches for over a week. The patient sleeps well, the bowels are open, the expression is improved. She complains of loss of flesh and spells of dizziness and weakness. The heart is irritable, the pulse running up to over 100 at times; there is a pruriginous eruption on the back, chest, and limbs. Temperature, 98.2° F.; tongue clean; appetite good. Urine contains no albumin. There is excessive thirst and some sweating.

The thyroid tabloids were continued, and two minims each of tincture of digitalis and strophanthus were ordered to be given four times a day. For the eruption a mild solution of carbolic acid was given.

March 27th.—A further reduction of the goitre has occurred; no return of headaches; skin normal; the eruption has vanished, but the fluttering sensation in the region of the heart persists.

April 5th.—The tumor in the neck is scarcely perceptible. There has been one slight headache since my last visit. Enunciation distinct and without hesita-

tion; face full of expression; eyes clear; œdema completely gone. Pulse, 92; temperature, 98.8° F. Urine normal; specific gravity, 1.020. There has been a loss of over twenty pounds in weight since beginning treatment.

April 20th.—Tumor gone; a flabby tissue feeling like an empty sac can be indistinctly made out. There is excessive sweating.

The digitalis and strophanthus were discontinued, and the thyroid extract was reduced to one five-grain tabloid a day.

I saw the patient at frequent intervals until June 3d, when all treatment was stopped.

On July 20th the patient returned, stating that she had remained well until three days before, when the severe headaches had reappeared. The thyroid gland had not enlarged, and there were no other symptoms of a return of her former disease. I ordered one five-grain tabloid of the thyroid extract daily for two weeks.

At the present writing she is taking the above-mentioned dose for two weeks every second month, and the disease is apparently held entirely in abeyance. I believe the headaches above noted were premonitory to the return of other symptoms, which were checked by prompt recourse to the thyroid extract. Dr. George R. Murray, to whom we owe the introduction of thyroid feeding in myxedema, in a paper read before the British Medical Association, in July, 1895, states as a result of his experience that "a relapse might be expected in about one hundred days after a patient had given up the dose of the extract."

An additional interest is given to the case I here report, in that the patient's mother suffered from a tumor in the neck, presumably thyroid, from the pressure effect of which she died. I am also informed that a young woman, living on a farm adjoining the one on which the subject of this article was born, has a goitre and has recently become insane, and is at present confined in an asylum.

The differentiation of this case of simple goitre from Graves' disease rests upon the absence of exophthalmos; the absence of tachycardia or even irritable heart until the treatment was pushed; the involvement of one lobe only of the thyroid gland; the presence of symptoms of myxedema, due to impairment of function; the relief of symptoms by the administration of thyroid extract.

689 LAFAYETTE AVENUE.

RUPTURE OF THE URETHRA.

BY H. A. GATES, M.D.,

DELHI, N. Y.

I WAS much interested in the discussion at the meeting of the Practitioners' Society of New York, April 3d, of the paper of Dr. R. F. Weir, regarding the treatment of ruptured urethra, as it was my fortune to encounter one of those rare cases recently, which I beg to report.

Mr. B——, aged forty-two, fell astride of a wagon wheel from a hay mow at 9 A.M., September 6th, and sent for his physician at 3 P.M., because of inability to void his urine. The latter made ineffectual attempts to pass a catheter, and sent for me, but I was also unable to pass the instrument. These attempts were followed by a discharge of blood from the meatus; there was extensive swelling of the scrotum and also of the perineal region, but no lesion of the skin.

I advised and performed perineal section on September 7th, and found extensive extravasation and clot, and entire severance of the urethra in the posterior part of the bulbous portion, the ends being at least one and one-fourth inches apart; the laceration was very

extensive, and it was impossible to locate the posterior portion at first, even after irrigating the tissues. I, however, resorted to the device of directing an assistant to press gently, with both open hands, over and on the fundus of the bladder, when the orifice was located by the escape of urine. A soft catheter was passed into the bladder through the meatus, and fastened. No attempt was made to approximate the divided ends of the urethra at this time, on account of the extensive injury and extravasation. Afterward the tissues on either side of both the anterior and posterior portions of the divided urethra were deeply caught with silkworm ligature and drawn together. This procedure brought the ends of the divided urethra well together over a soft catheter, which had been previously passed through into the bladder.

The perineal wound was kept clean and allowed to unite by granulation, and the bladder kept washed out with boric-acid solution and glycerin. When the wound healed the sound was substituted for the catheter, and the patient is now entirely well.

It would seem to me that the suprapubic opening is very seldom required, that repair of the urethra may be shortened by stitching, but that most of the firm union comes by granulation long afterward.

A CASE OF CHRONIC APPENDICITIS.

By S. P. PRESTON, M.D.,

LYNCHBURG, VA.

E. W.—, male, aged thirty-four; occupation, business man. Family history good. As far back as the patient can remember he has suffered pain in the right iliac region, especially after increased exertion. On his remaining quiet, the pain was of a dull, aching character, and most acute anteriorly above Poupart's ligament, ranging back toward right lumbar region. On exertion the pain would become intense or aggravated even by walking, and at times he would be seized with a paroxysm of the most agonizing pain, lasting for perhaps half an hour or longer and abruptly ending, followed by sleep; and on his awaking the pain in its acute character had disappeared, leaving the dull, aching pain as before, but aggravated. Thereafter he would not suffer enough inconvenience to keep him from his ordinary daily affairs.

Status *præsens*: The patient is a large, powerfully built, well-nourished man; complexion dark, at times bluish. He states that although the pain is much less than it was at former times, he still suffers considerably; in fact, during his whole life he has never been absolutely free from it. The appetite is good. The bowels are extremely constipated at times; the stools are well colored; the urine is normal. Physical examination shows a spot of tenderness three inches above the middle of Poupart's ligament, two inches within the right superior spine of the ilium, and a line of tenderness extending back to the lumbar region, parallel with the crest of the ilium and about an inch above it, and becoming more sensitive at its termination to the right of the spine. When the patient suffers with the acute paroxysm, the spot in the iliac region becomes exquisitely painful. The pain is somewhat relieved by warm applications, and is especially lessened by flexion of the thigh on the abdomen. Patient states that during the acute paroxysm, priapism often occurs. In the past six years the pain has become progressively better, owing to his having paid better attention to his health; but he is still annoyed to such an extent as to seek constant medical advice.

Diagnosis: Chronic catarrhal appendicitis: dilatation of appendix, with formation of stercoliths, and

expulsion of concretions at times into the cæcum (as indicated by acute seizures, short in duration).

Indications for treatment: An exploratory incision is advised, with excision of the appendix, if it be found diseased as supposed.

AN EXCEPTIONAL LAPAROTOMY.

By JAMES E. MOORE, M.D.,

MINNEAPOLIS.

In April, 1895, Miss A. M.—, aged twenty-five, came under my care at the Northwestern Hospital. She gave the history of having suffered a criminal abortion in November, 1894, which was followed by an abscess to the left of the uterus, which finally opened near the umbilicus. After many weeks of suffering the patient got about, with a sinus near the umbilicus, which discharged both pus and fecal matter.

When I first saw her she was weak and greatly emaciated. Her appetite was good, but digestion poor. Diarrhœa was present most of the time. There were at this time around the umbilicus five openings discharging fecal matter. The abdomen was slightly distended and yielded tympanitic resonance everywhere on percussion. The patient was weak, suffering, and in an altogether pitiable condition, so I concluded to try to relieve her.

Upon passing probes into the fistulæ about the umbilicus, it was found that all led to one cavity underneath. They were thrown into one by an incision and a cavity was found underneath the umbilicus, seemingly in the abdominal wall, which communicated with the abdominal cavity by one small opening. I removed the umbilicus completely to gain better access to the deeper opening. A probe passed into this opening seemed to enter the intestine. There was tympanitic resonance just below, so I made an incision in the median line, in order to get into the abdominal cavity and reach the bowel into which the fistula opened. Very much to my surprise and disgust, gas and fecal matter appeared in the wound as soon as I got through the abdominal wall. It seemed certain that I had opened into adherent intestine: but upon introducing a finger I found that I was in the general abdominal cavity, and that the tympanitic resonance, supposed to be due to distended bowels, was due to gas in this cavity.

I then began with the fistula at the umbilicus, and laid the abdomen open well down toward the symphysis. After washing a large quantity of fecal matter from the abdominal cavity, I found that the intestines were all bound down to the posterior abdominal wall in a mass, and that by introducing the nozzle of an irrigator underneath one side of this mass, fecal matter could be washed from the other side. It was simply impossible to form any idea as to the locality of the opening into the bowel, so I introduced some iodoform gauze into the wound and left it open. After a few days the patient began to improve, but the dressings were filthy in the extreme; so I removed all of the gauze and ordered the abdominal cavity to be flushed with warm water twice a day or oftener, if necessary. The patient gradually improved, and the opening in the bowel closed. The large abdominal wound closed, the abdomen filled out, and at the end of three months the woman was in perfect health and had a very presentable abdomen. I have recently learned that she is employed in a neighboring city as a domestic, and that she enjoys good health.

The Offspring of the Corset is what a contemporary calls the obstetrical forceps.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATH OF SIR J. E. ERICHSEN, F.R.S., LL.D., ETC.—
BRITISH ASSOCIATION—BANQUET AND SYMPOSIUM TO
SIR JOSEPH LISTER—METRIC SYSTEM—EVIDENCE AT
INQUESTS—THE LATE DRS. MILLETT AND POWELL.

LONDON, September 25, 1896.

SIR JOHN ERICHSEN died on Wednesday (23d). His name will be familiar to all your readers and his personality will be remembered by not a few who welcomed him to the States in 1873. He was a man of pleasant presence, courteous in manner, upright in all his relations—in a word, a gentleman. All who knew him—and who among us did not?—speak well of him. He had retired from active practice, but continued to be a conspicuous figure in professional circles. It seems a long time since he used to come down to lecture in his faultless attire and new primrose gloves, which some thought made him the dandy of University College, but his geniality made him a favorite with most of his pupils. His intimates could see that he had been breaking for some time. He admitted that the less he did the better he felt. Occasional attacks of angina pectoris had troubled him of late and loss of control of some muscles lasting only a few minutes had also occurred. On the 17th inst. he retired at night in his usual health, but the next morning his valet found him to be unconscious. He soon recovered consciousness, but aphasia and hemiplegia remained. On Tuesday the lungs became engorged, and he died on Wednesday afternoon, the last illness being thus under a week's duration.

Erichsen's "Science and Art of Surgery" is known everywhere as the most successful surgical text-book of this generation. It first appeared in 1853. The fifth edition was extended into two volumes in 1879, and it has continued in that form, the tenth edition being published last year. It has been translated into German, Spanish, and Italian. The American issues have been very large.

Besides this *magnum opus* he wrote a small work on "Railway Injuries" and one on "Hospitalism," and contributed to the societies and journals. In his early days he received the Fothergillian medal of the Royal Humane Society for his work on "Asphyxia." He became a member of the College of Surgeons in 1839, a fellow in 1845, and served all the offices in due course up to the presidency (1880). So at University College, of which he was an alumnus, he became professor of surgery and surgeon to the hospital, and held these offices until he resigned. He was elected president in 1887 and retained this post until his decease. He was the recipient of honors from academies, universities, and societies in various countries and last year was created a baronet.

The British Association continued its sittings at Liverpool until Tuesday. Besides the proceedings I have mentioned, there were interesting papers in the physiological section and a good number of medical men in this and other sections joined in the discussions.

The chief event was perhaps the splendid banquet to Sir Joseph Lister given by the medical institutions of the neighborhood, at which more than three hundred and fifty of his admirers were present. In the galleries about one hundred nurses occupied seats and were in uniform. They were highly complimented by Sir Joseph in returning thanks for the toast of his health proposed by Dr. Caton and received with enthusiasm. There was another large gathering in his honor at a symposium held on Friday.

In the section of mechanical science Sir Frederick Bramwell ridiculed the metric system in a light humorous way, and said that in France he found when a sum was in metres or kilograms the ordinary Frenchman first worked it out in fractions and then converted it into decimals. So he held the English system to be better, as it only required the work to be gone over once.

The metric system had been ably advocated by Sir Douglas Fox in his address as president of this section.

We are accustomed to curious incidents at inquests and often have to complain of coroners, but it must be acknowledged that doctors do not always shine in these courts. Only on Wednesday the newspapers reported a case in which a jurymen remarked in the midst of his evidence that the doctor seemed "slightly fogged," and after he left another said he "was at least a rum 'un." And looking at the answers he gave, I cannot say the criticism was unjust. Take this colloquy between coroner and doctor and draw your own conclusions. "Then you say death was due to fatty degeneration of the heart?" "Well—er—not exactly." "Was it due to heart disease then?" "Not valvular disease." "Syncope then?" "No, I should say not." "Well, doctor, tell us the cause. You have made the post-mortem." "I think the state of the heart prevented proper circulation." "Then you mean heart failure?" "Well, yes, but not in the regular way." "Really, doctor, I do not understand you." "Well, the heart didn't stop in the manner as if he had taken poison." "But you don't suggest he had taken poison?" "Oh, dear! no. I think if he had been woke up he might be alive now." "Well, shall I be wrong to certify that he died from heart failure due to fatty degeneration?" "No, I think that is the real cause."

Mr. George B. Millett, medical officer of health for Penzance, died on the 17th inst. He was a well-known authority on Cornish antiquities, president of the Penzance Institute, vice-president of the Antiquarian and Natural History Society, and honorary surgeon to the Infirmary.

A sad case comes to me from Ireland. Dr. G. H. Powell, of Toomevara, was eating an apple, when a wasp which was in the core stung him on the tongue, and he died in three hours from the glossitis induced. He was only thirty-five years of age.

OUR PARIS LETTER.

(From our Special Correspondent.)

BEGINNING OF THE MEDICAL YEAR—LOWEST DEATH RATE IN PARIS KNOWN SINCE 1879—DIPHTHERIA NO LONGER FEARED—THE ACADEMY OF MEDICINE—THE ACADEMY OF SCIENCES—NEW OTOSTETHOSCOPE—PROPOSED LAW AGAINST THE CREATION OF NEW FACULTIES OF MEDICINE, ETC.

PARIS, October 1, 1896.

It is the beginning of the medical and academic year. Janitors are sweeping and cleansing laboratories, amphitheatres, and libraries; every day brings back from their vacations one or more professors or some hospital and private-practice celebrity, students are seen once more in the Quartier Latin, and professional Paris is getting into swing again.

We begin the year with a clean bill of health as regards epidemic and zymotic diseases; that is to say, the lowest record since the service of the Statistique Municipale of the city of Paris has been established, which was in the year 1879. The number of deaths for the thirty-eighth week of the year is six hundred and ninety-eight—even in the thirty-fifth week the mortality was only seven hundred and fifty-three, a very low figure for that or any time of year. Zymotic

diseases continue to be rare; for instance, there were but six deaths for the week just ended instead of twelve, the average, from typhoid fever; one from small-pox instead of two, the average; measles three, instead of six, the average; scarlet fever two, average; whooping-cough two instead of five, the average. Finally, diphtheria has caused no deaths in the city of Paris. There were, it is true, two deaths in the hospitals, but these were of children from the country who had been brought to Paris to be treated. This total absence of deaths from diphtheria is remarkable, for previous to 1893 the average of deaths from this disease was twenty during the weeks of September and the number of deaths never went below seven, which figure it reached in the thirty-sixth week of 1886, which was regarded as very exceptional. During the last few years, thanks to the discoveries of modern science and above all to orrhoterapy, diphtheria has become much less deadly, and already the thirty-fifth week of 1895 has passed without a single death attributable to that malady. Whatever may be said for or against orrhoterapy, these facts are irresistible. It is now only necessary to detach from the pharynx or tonsils a small portion of suspected membrane, to make a bacteriological examination and diagnosis at the same moment, to inject a few grams of antidiphtheric serum, and we master one of the most if not the most dreaded and fatal of all diseases, thus relegating gargles, washes, applications, caustics, and cataplasms to the past.

As might be expected so early in the year, there is very little doing at the Academy of Medicine or at the Academy of Sciences.

There was a meeting of the Academy of Medicine on September 22d. Professor Debove read a report on Dr. Clozier's work on "Toxæmia in Cases of Gastro-Enteropathy." Professor Debove maintains, contrary to the opinion of the author, that the nervous complications in cases of gastro-enteropathy are not due to digestive troubles but to a general neuropathic condition. Dr. Clozier assumes that the stomach and intestines pathologically affected manufacture poisons and that these poisons engender a toxæmia, which in turn provokes the appearance of nervous phenomena.

This hypothesis not being justified by the facts upon which the author bases his opinion, it appears much more natural, in the reporter's judgment, to suppose that the patients of Dr. Clozier were affected by divers nervous disturbances, among them disorders of the intestine, than to admit a production of intestinal poisons, a toxæmia, and nervous phenomena dependent upon that toxæmia.

I would note in this connection that, notwithstanding the opinion of so eminent a physician as Professor Debove, in the practice of internal medicine many cases of auto-infection or toxæmia are met with and that this auto-infection manifests itself not infrequently in the nervous system—usually through irritation of the sympathetic directly due to the absorption of toxins or ptomains, for the development and multiplication of which the intestines, above all tracts or organs of the body, are the most fertile ground; and I am now treating a case of polymorphous eczema of nervous origin caused by the generation of just such enteric poison.

Professor Debove was followed by Dr. Bendersky, of Kiev, who spoke on auscultatory percussion as a method of delimiting internal organs. This method consists in percussing lightly the region of a given organ and that the sound, which cannot be heard at a distance, may be gathered by the ear, Dr. Bendersky uses a soft stethoscope like those often employed by American and English diagnosticians (really a modification of Flint's double-tubed bell-shaped instrument); only Dr. Bendersky's stethoscope has one long

tube of one hundred and forty to one hundred and fifty centimetres, one end of which is adapted to the base, the other being fastened to the end of an otoscope. This is placed against the ear. With his left hand he steadies the base on the organ and percusses with his right hand. The sounds or resonance, as the case may be, are thus brought out very clearly, and may even be heard through the clothing.

Dr. Bendersky added a few words on gastric mobility, stating that the diagnosis of gastroptosis was made when the inferior limit of the stomach passed below the umbilicus—and that this diagnosis was greatly facilitated by the above-mentioned method. Dr. Le-reboullet read the oration that he delivered at the grave of Dr. Rochard, recently deceased.

At the Academy of Sciences on the 14th of September Dr. Joachimsthal made a communication upon a new adaptation of the muscles of the leg after the cure of clubfoot. He said, in substance, that a patient after the cure of a clubfoot had recovered the functions of walking; nevertheless the gastrocnemian muscles presented a deformity characteristic of diminution in the extent of movement of those muscles; the gemelli were considerably reduced in size, and the relief of the upper calf of the leg was hardly half its normal length. As regards the protuberant outline of the soleus, that had disappeared entirely. Dr. Joachimsthal in order to ascertain whether the modification of the muscles was due to any change in the length of the calcaneum, photographed the skeletons of the two feet of his patient by means of the Roentgen rays. These photographs showed on the abnormal side a marked atrophy of the calcaneum, but without change in the length of that bone as regards the lever of the tibio-tarsal articulation. Then photographs were made of the two feet in their positions of flexion and extension. The second photographs showed plainly what might already have been deduced from the first, viz.: that the extent of movement on the abnormal side was extremely limited. It was therefore to this cause that the diminution in length of the fibres of the gemelli muscles must be attributed. These muscles, however, had retained their action as flexors of the knee: this explains their partial conservation, while the soleus, having its function abolished by the tibio-tarsal ankylosis, appeared to have been completely effaced. This case is not only a remarkable example of what the Roentgen rays have done and are doing for surgery, but also of the adaptation of muscles to the change of their functions in general.

Faculties of medicine are not numerous in France, there being only six on the official list, these being part of a composite whole designated as the University of France. And yet M. Deandreis, senator, has filed in the "bureau" of the senate a proposition that no new faculty shall be created without the enactment of a law. The principle of protection as regards medical schools and medical practice in France is, metaphorically speaking, a cast-iron one.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE PSYCHOLOGICAL CONGRESS.

BERLIN, October 2, 1896.

At present quiet reigns supreme, for all local medical meetings have ceased. The International Psychological Congress held its third session at Munich a few days ago. In all about one hundred and fifty medical papers were presented and read. About four hundred and fifty men from all parts of the world participated.

The congress was opened by the president, Professor Stumpf, of Berlin. He gave a very interesting review of the scientific work performed by this body

since its first meeting, which took place at Paris in 1889. The work was divided into five different sections, viz.: I. Anatomy and Physiology of the Brain and the Senses. II. Normal Psychology. III. Psycho-pathology and Criminal Psychology. IV. Psychology of Sleep, Dreams, and the Hypnotic Condition. V. Comparative and Pedagogic Psychology.

After the address of welcome was delivered by the minister of state, the mayor of Munich followed. Then lastly the rector of the Munich University spoke. These welcomes were answered by Richet of France, Baldwin of America, Sedgwick of England, and Tokowsky of Russia.

Professor Richet then spoke on "Pain." He regarded pain as a sensation given to us by nature which prolongs life. Pain is called forth by any ill-treatment of the nerves which changes their condition. Richet expressed the belief that even smell and taste could cause pain under certain conditions.

Professor Flechsig next spoke on "The Associated Centres of the Human Brain." He did not like to see the brain divided into lobes, but rather into "areas" and therewith communicating filaments, or as he termed them "Leitungsbahnen." The centra for the senses on the surface of the brain he considers very small. They form four distinct areas or parts. In these four areas there are neither motor nor sensory communications. This paper, which was profusely illustrated by brain specimens, aroused great interest and created an animated discussion. Dr. Wendensky, of St. Petersburg, believed he could prove by animal experiments which part of hemisphere of brain was used. Dr. Patrizi found that music induced a greater blood supply. Dr. Epstein found that light influences markedly the circulation (vascular), the strongest effect being produced by red; the weakest was that of green light.

Dr. Liszt, of Halle, read a paper on "Medico-Legal Responsibility." This he believed should be determined by the age; so, for example, according to German law responsibility is not determined below the twelfth year. He did not believe that a chronic criminal is to be held absolutely responsible for his deeds. Formerly all weak-minded people were regarded as criminals. He recommended that all habitual criminals should be put into insane institutions, although he believed that they should be kept separate and classed as criminals.

Dr. Lehmann, of Copenhagen, had devoted some study to the question of "fright," as, for example, its influence on the pulse, and had found at times permanent conditions caused by this influence.

The "Pathology of Memory" was the subject of the next paper by Dr. Strumpell, especial attention being devoted to traumatism, epileptic attacks, and intoxication.

A most interesting subject was brought out by Dr. F. C. Müller, of Munich, in a paper entitled "The Relation of Suicide to Alcohol." He found that both the consumption of alcohol and the number of suicides have increased very much lately. In thickly populated districts, workingmen's towns, the number of suicides is enormous and the alcoholic consumption is positively the cause of the suicide, inasmuch as neurasthenia is caused by alcohol. It is false to believe that beer is not detrimental or less so than whiskey. In countries where whiskey is prohibited, *e.g.*, in Norway, the number of suicides is surprisingly small. The author believed that alcohol so completely demoralizes the human being that suicide is a sort of relief to him. He was sorry to see alcohol introduced into therapeutics, for its ill-effects are far greater than its benefits. He believed alcohol to be a poison and thought that physicians should take a decided stand against it. In fact he believed we should be as careful in prescribing alcohol as we are in prescribing morphine or digitalis.

An interesting communication was one by Dr. Bonjour, of Loussanne, in which he reported the treatment of warts by suggestion. The author claimed to have been cured of a wart by suggestion.

Dr. Ebbinghaus read a paper on the necessity of examining school children to determine their mental sufficiency or insufficiency.

Along with these papers there was an exhibition of various apparatus and one of especial value built by the Berlin Electrical Company for Roentgen illumination. All the internal viscera, more especially the heart, stomach, and diaphragm, and the movements of the latter, could be plainly followed on the fluorescent screen.

Professor Strumpf adjourned the congress, which had lasted four days, until 1900, the next session to be held at Paris the year of the exhibition.

"THE APPENDICITIS CONTROVERSY."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As a constant reader of the New York MEDICAL RECORD, I have taken a great deal of interest in the recent discussion carried on in your columns about the effectiveness of the operation for the removal of the appendix vermiformis in cases of inflammation of the appendix. I am, as a section of the Populists call themselves, a middle-of-the-road man, believing that while the operation has saved a large proportion of patients, it has also killed not a few of them—not for lack of skill in its performance, but for lack of judgment in the selection of cases to be operated on. Nowadays it is quite the style to belittle the physician and to elevate the surgeon. I honestly believe that the mortality arising from operative surgery would be decreased if the physician were given a little more consideration. To differentiate between the qualities which enter into the makeup of the successful physician or surgeon would take up too much of your space, even if I were capable of doing it properly; so I will content myself with detailing a brief and incomplete history of the following case, which may, perhaps, serve as an illustration of the point I wish to make. I was the family physician of the patient, but, as the history will show, was not responsible in any way for the treatment.

A telephone message was sent to my office on the evening of September 15th, asking if I was at home. The sender of the message was the father of the patient, who said if I was at home he would take his son down to my office, as he had been complaining of stomachache. On being told that I was absent and would not be home for some hours, he asked that I call at his house the next morning to see the boy. The boy, R. H.—, eleven years of age, had returned from the country the previous Saturday, September 12th, and, as his mother expressed it, "was in the pink of condition, never looked better in his life." On Sunday, September 13th, he complained of pains, supposed to be colicky and attributed to the fact that he had eaten some muskmelon the previous day. His mother gave him a dose of rhubarb and castor oil, which opened his bowels freely, and the pain ceased. He was up and out during the morning; toward evening the pain returned, but was less violent. He vomited several times during the day. Hot applications were imperfectly applied, and in the evening he went to sleep and did not again complain until early on Monday morning. He kept to his bed Monday (September 14th), resting at intervals and not complaining of pain. Thus the time passed until Tuesday (September 15th) evening, when, the pain having returned and in a more violent form, the father telephoned to my office. The parents became alarmed and sum-

moned a neighboring physician about nine o'clock that evening. The doctor remarked that the patient made a correct diagnosis of his own case, as he placed his hand over his appendix, pointing out the seat of trouble.

The physician recommended his immediate transmission to the hospital, and removed the appendix and had his patient resting in bed by 11 P.M. the same night. The father of the patient told me that the doctor said: "There was no pus found in the appendix, but it was in a catarrhal condition." The following day (September 16th) was passed comparatively quietly, with little rest, occasional vomiting, and more or less mental excitement, due probably to the ether inhaled.

I saw him, not in my professional capacity, but as a friend of the family, on Thursday (September 17th). I took his pulse very carefully, and found it beating 120, thready and dicrotic. To me he seemed dying, but I learned that the attending physician had expressed a hopeful opinion of his chances. He declined day by day, his temperature varying from 99° to 103° F., pulse from 110 to 140, until the following Monday (September 21st), when he died at about 5 A.M.

Now, here was a healthy boy, suffering from appendicitis, who seemed to start for the grave, not rapidly but gradually, from the moment of operation. At no time after the operation did there seem a chance for his recovery. The operation was uncomplicated, as shown by the rapidity with which it was done. Would it not be reasonable to infer that the wrong time was chosen? Might it not be even inferred that without the operation the patient would have recovered? Even with the operation, the chances of recovery would have been better if it had been delayed for twenty-four hours, during which time every effort might have been made to reduce the tendency to general peritonitis by warm applications effectively applied, by the administration of opium, and the consequent rest. In cases like the above, the physician, in my opinion, would be a very important factor in determining the ultimate fate of the patient. His training and his powers of observation are very different from those of the surgeon, who is always looking for the concrete, while the physician takes both abstract and concrete into consideration.

FREDERICK J. HALTON, M.D.

BROOKLYN, N. Y.

CONGENITAL INFERIOR INCISORS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The undersigned was called February 22, 1896, to Mrs. L— who was in her second confinement and at the eighth month of gestation. Twins were born and on examination one of them was found to have two congenital inferior incisors. The teeth were projecting probably one-sixteenth of an inch above the gums but were very loose and movable, and could have been removed with the fingers. The children were both small, poorly developed, and rachitic in appearance. One tooth disappeared at the tenth week and the child died the twelfth week. This occurred suddenly and away from home. The physician who was called found it in convulsions and considered death due to meningitis. The remaining tooth was removed and given to me. The case was seen at various times by a large number of medical students and physicians, was shown at the April meeting of the Obstetrical Society of Cincinnati, and the tooth was presented to the Cincinnati Academy of Medicine. None of the gentlemen had ever seen a similar case. Margitot, Schürig, Pliny, Bartholin, Ballantyne, Vargas, Buist, Mackenzie, Forchheimer, Jacobi, and Pierce have written on the subject.

E. S. MCKEE, M.D.

CINCINNATI, OHIO, October 6, 1896.

MOVABLE EARS IN MAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with great interest an article in your issue of September 12, 1896, on "Rudimentary Organs," by Cora H. Flagg, M.D. In reading what the author says of the external ear, I remembered having seen two or three people who were able to move voluntarily their ears. There is a good anecdote of a German professor of anatomy (of course such things occur only with German professors) whose son possessed that exceptional gift. Every year, when the time came, the professor used to take his son to the class and at the proper moment said to him: "Now, Charlie, move your ears for the gentlemen."

I once knew an old man from Central America whose ears had a peculiar animal-like form. They were elongated and pointed above and covered all over with upward-tending hair of about one inch in length, forming at the point a brush as we find it on the ear of the squirrel.

F. SEMELEDER, M.D.

CORDOBA, STATE OF VERA CRUZ, September 28, 1896.

"COLLAPSE FROM EXCESSIVE VOMITING."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was much interested in the article appearing in the MEDICAL RECORD of September 26th, by Carlos C. Booth, M.D., of Youngstown, O., relating the history of a case entitled "A Case of Collapse from Excessive Vomiting Successfully Treated by Intravenous Infusion of Saline Solution." He states that he found his patient, at 5 P.M., July 28, 1896, vomiting large quantities of fluid, associated with general cramps, for which he administered a large hypodermic injection of morphine, and repeated the same large dose at 8 P.M. On the following day, "although he had received large hypodermic injections all this time at intervals of two or three hours, the vomiting continued." July 30th, at 9 A.M., he was still vomiting, and from excessive loss of fluid (?) was rapidly approaching death. Now the treatment was changed to nitroglycerin and strychnine.

As I look upon the situation, it was the patient's good fortune when the doctor began the use of the two last-named drugs and stopped the morphine, as it is well known that in many the use of morphine produces vomiting and depresses and weakens the vital forces, especially in those unaccustomed to its use, and particularly so when used in "large doses" and repeated at frequent intervals for a considerable time. I believe the doctor can congratulate himself, not only upon the use of the saline solution, but upon the disuse of the morphine and the substitution in its stead of nitroglycerin and strychnine. I further believe that too great caution cannot be exercised in the administration of morphine in large and repeated doses, especially at a time when the patient is suffering from a disease that is prostrating in its effect, as collapse may precipitate the case beyond reaction before we are aware. In the case to which the article refers, there was no secretion of urine from July 28th to the 31st. I believe this condition of suspension of the function of the kidneys was also largely, if not wholly, due to the use of the morphine rather than to the disease itself.

F. L. SANTWAY, M.D.

THERESA, N. Y.

Blood Purifiers and Nerve Tonics.—The chemist of the Massachusetts board of health has made an analysis of ten of the most popular nerve tonics and blood medicines, and has found them to contain from 7.9 to 26.2 per cent. of alcohol.

Surgical Suggestions.

Tuberculous Glands should be removed without rupture of their envelopes, as otherwise systemic infection is liable to result.

Puerperal Septic Disease.—Dr. G. A. Solovioff, of Moscow, in discussing the treatment of diphtheroid lesions of the womb and vagina in puerperal cases, recommends painting the affected areas with iodine tincture.

Compound Fractures.—Tyson says the time has come when all compound fractures should be treated by uniting the ends of the bone, the wound being thoroughly irrigated. Five cases of apparently hopeless fractures of the ankle-joint are reported by Bach as giving very good final results.

Epilepsy.—Among the causes of reflex epilepsy may be mentioned ingrowing toenails and even corns, scars about the limbs, disorders of the genitalia (phimosis with adhesions, irritative conditions of the clitoris and mouth of the vagina), pinworms, rectal disorders, and even defective teeth.

Neoplasms.—Dr. Wiggin (*North Carolina Medical Journal*) says that neoplasms occur with greater frequency in the female than in the male subject. Statistics show that the breast, next to the uterus, is the most usual site of these morbid changes—seventeen per cent. in the latter. Williams found, in a collection of 13,824 primary neoplasms, 2,397 cases in which the female breast was affected.

Acute Osteomyelitis of Long Bones.—Dr. Walter is reported in the *Revue de Chirurgie*, December, 1895, as saying that: 1. The results of treatment depend on the thoroughness and promptness of operation. 2. The bone shaft must be freely opened; thorough curettage, disinfection, and drainage must be employed. In mild forms bone trepannage with local and constitutional measures may succeed.

Shock.—In France, for cases of severe shock from hemorrhage, instead of the intravenous injection of normal salt solution (six parts salt to one thousand parts sterilized water), hypodermic injections of Hayem's serum are employed. This serum consists of five grams of sodium chloride, twelve grams of sulphate of sodium, and one litre of distilled water. This fluid is sterilized by being brought to the boiling point.—*Medical Recorder*.

Varicoceles.—Dr. Dardignae (*Revue de Chirurgie*, September, 1895) reports eighteen cases of resection of the scrotum for painful varicoceles. The resection was bilateral when the varicocele was double or very large and the scrotal tissues were badly stretched. In three cases the resulting hæmatoma made it necessary to relieve tension by cutting the stitches, but these were the only unfortunate events in the series. Most of the operations were done three to five years ago, and the patients express themselves as perfectly satisfied with their condition. All have been actively employed and some wear no suspensory.

Phlebitis.—Dr. White treats phlebitis arising as a sequela of typhoid fever as follows: He elevates the limb and keeps it at rest. He applies over the vein an ointment of equal parts of the ointments of belladonna, mercury, compound iodine, and cosmoline. He applies a flannel bandage to secure a proper amount of pressure. As the swelling subsides, cautious massage is applied. Rest is imperative, otherwise there is danger of embolism and consequent paralysis.

Osteomyelitis.—Dr. Wyeth says that when osteomyelitis is present, it is not necessary to amputate the whole limb, as has been taught, and many a leg has been sacrificed that might now be saved. Bones affected by osteomyelitis can be saved, provided good drainage is established. In the femur a large opening just above the knee, in the humerus just above the elbow, is to be made, and the canal thoroughly curetted from one end to the other, under irrigation with some powerful antiseptic solution, and a large drainage tube inserted, with iodoform gauze stuffed lightly around it. Antiseptic irrigation has to be made every day or two, the tube being gradually withdrawn. This practice has been attended with invariable success.

Prognosis in Cerebral Hemorrhage.—Dr. Barr, in a lecture delivered at the Leeds General Infirmary, concludes as follows: In any case of apoplexy due to hemorrhage into the hemisphere, if renal disease, Cheyne-Stokes respiration, or hyperpyrexia, either or all of them, or two of them, are present, the patient will almost certainly die. If no one of these is present and does not supervene, he will probably recover, regardless of the degree or duration of insensibility. Diabetes, chronic alcoholism, typhoid fever, or extreme anæmia (idiopathic) exert an effect just as fatal as associated disease of the kidney in hemorrhagic apoplexy.

Mammary Growths.—Dr. Rodman closes a paper on the subject with the following propositions: First, all mammary growths should be removed at once, for innocent tumors carried for a long time become a menace. Second, the complete operation should always be done in cases of malignant disease. Third, in nearly every case it is simply impossible to detect enlarged glands until the axilla is opened. Keen says that he cannot do so once in ten times. Fourth, the mortality should be with average operators about three per cent. Fifth, a radical operation should promise from twenty-five to fifty per cent. of permanent cures, according to the time when patients apply. Sixth, when in doubt, operate; never wait for symptoms.—*American Practitioner and News*, March 7th.

Cerebral Tumors.—Dr. H. G. Brainerd, professor of diseases of the mind and nervous system, University of Southern California, says the symptoms of cerebral tumors are of two kinds, viz.: those of cerebral irritation; and those arising from involvement of definite areas, which we call focal symptoms. The classical symptoms of cerebral irritation are: Pain (exacerbations paroxysmal), vertigo, vomiting, convulsions, slowness of speech, mental hebetude, emaciation, slow or irregular pulse, and double optic neuritis—all of which are increased by meningitis or softening, one or both of which usually accompany tumors. Focal symptoms vary with their location, the rapidity and character of the tumor, and may be either sensory or motor—which latter may be either convulsive or paralytic.

Only Once Before.—Dr. Keen, of Philadelphia, tells a good story of the famous Langenbeck. A patient was brought in whom he had examined previously and whose case he had diagnosed as a malignant tumor of the breast. He proceeded to remove the entire gland in a rapid and very brilliant manner. While an assistant was dressing the wound, Dr. Langenbeck, in the presence of the class, cut into the tumor to verify his diagnosis. The result was a liberal discharge of pus. He looked surprised, but with great composure remarked: "I never did that but once before in my life." An incision before removing the breast would have saved the great clinician some humiliation and the woman her mammary gland.

New Wound Dressing.—The Japanese surgeons during the late war employed as a dressing for wounds the ash of rice; the contained carbonate of potassium making it antiseptic.—*Medical Age*.

Painful Urination.—Dr. Parker (*Kansas Medical Journal*) says: "Causes other than gonorrhœa are as follows: Aerid vaginal secretions, endocervicitis, endometritis, discharges from malignant disease, pus from a healthy abscess, powerful injections, rough catheterism, passage of stones, and other causes."

Vulvo-Vaginal Catarrh.—Dr. Randolph Wilson, of Baltimore, Md., says that in his experience nearly all cases of vulvo-vaginal catarrh are of gonorrhœal origin; even in children as young as two or three years this is true, infection occurring through soiled linen, etc. Dr. Lanphear, of St. Louis, has recorded one case in a child of eight months, the nurse girl wiping her infected vulva with the napkin which she subsequently placed on the baby.

Lacerated Wounds of the Hand.—In cases of severe injury to the fingers by laceration or contusion, put the entire hand into a very ample soaking-wet dressing. Do not even trim off a piece of flapping skin. Incision for drainage is all that is allowable until healing is very well under way or even quite complete. You may then look over the ground and see whether it is worth while to sacrifice anything. A half-inch of boneless finger may be of incalculable value to the possessor.—*Cincinnati Lancet and Clinic*.

Colles' Fracture.—The splints should never be allowed to remain more than five or six days at the beginning of treatment, and after that not more than three days at any one time. It has always been my practice to remove all dressings on the fifth day and examine the condition of the arm, using massage and slight passive motion. After that I remove the splints and use massage and passive motion every second day until union is complete, which is from four to five weeks later, according to the age of the patient.—Dr. BEATTY, *Maryland Medical Journal*, April, 1896.

Hip-Joint Disease.—In young children the very beginnings of hip-joint disease are announced by muscular twitchings during sleep; added to this, the subject is irritable, the secretions are disturbed, the appetite is fictitious, the muscles are flabby and shrunken away on the affected side, the countenance is pale, and the signs of illness are very apparent. Soon follows a little limp in the gait, attended by pains in the knee or ankle-joint—not often in the hip. These pains are at first very slight and may escape attention, unless the medical attendant is very alert. A rise of temperature will sometimes be noticed in the evening, and it may be continuous; toward the last of this stage more or less spasm of the muscles will have supervened.—*Medical Arena*.

Indications for Nephrectomy.—Dr. Kuster (*British Medical Journal*) restricts this operation to the following conditions: 1. Tumors of the kidney. 2. Tuberculosis of the kidneys; experience has shown that renal tuberculosis occurs very often primarily and unilaterally; it affects the genitals and the lower urinary passages more frequently than some other parts of the body. Severe persistent catarrh of the urinary bladder is one of the first symptoms which tuberculosis of the kidney presents; in cases of this kind nephrectomy gives excellent results, and complete recovery ensues. 3. Suppurating kidney caused by metastatic processes and foreign bodies, especially calculi. 4. Renal hæmophilia. 5. Movable kidney. 6. Injury to the kidney. 7. Calculous diseases of the kidney. 8. Uretero-abdominal fistula.

Buried Sutures of Silkworm Gut.—Dr. Edebohls (*American Gynecological and Obstetrical Journal*, May, 1896) says: "Proof was thus forthcoming, in the course of time and in the shape of resurrected buried sutures, that aseptic burial and primary union did not always end the matter. The aseptically buried silkworm-gut suture did not always remain as an innocuous and encapsulated foreign body in the tissues, but in a proportion of cases—estimated in my experience at between five and ten per cent. of all sutures thus aseptically buried at the time of operation—the suture at a more or less remote period caused suppuration, and, either with or without extraneous help, found its way to the surface and was discharged. I have given up trying to make the cæliotomy incision exactly in the median line, but, with a number of other operators, prefer to make it through one of the recti muscles, a little to one side of the median line. The purpose is to get bare muscle surfaces on either side of the wound, which, when brought together by suture, will help by the strength of their union to make the cicatrix just that much stronger."

Gauze Dressing.—Dr. Martenson (*La Médecine Moderne*, February 22, 1896) prepares dressings as follows: Rolls of cheese cloth, about thirty yards, are placed in jars, and different kinds of gauze are prepared by the following solutions:

Carbolized gauze, five per cent.: Colophene, 50 parts; castor oil, 15 parts; carbolic acid, 28 parts; alcohol, ninety per cent., 207 parts. Three hundred parts by weight of this mixture to 500 parts of gauze.

The following may be used: Vaseline, 30 parts; carbolic acid, 28 parts; benzene, 242 parts. Three hundred parts to 500 parts of gauze.

Thymolated gauze: Thymol, 10 parts; spirits of turpentine, 3 parts; paraffin oil, 10 parts; benzene, 200 parts. Equal parts of the solution and of the gauze.

Sublimated gauze: Bichloride of mercury, $1\frac{1}{2}$ parts; chloride of sodium, $\frac{1}{2}$ part; glycerin, 15 parts; distilled water, 500 parts. Equal parts of this solution and of gauze.
